Introduction

1. Assume that the observed variable x is a random sample from an underlying process, whose true distribution $p_d(x)$ is unknown.

- 2. We attempt to approximate this process with a chosen model, $p_{\theta}(\mathbf{x})$, with parameters θ such that $\mathbf{x} \sim p_{\theta}(\mathbf{x})$.
- 3. Learning is the process of searching for the parameter θ such that $p_{\theta}(\mathbf{x})$ well approximates $p_{d}(\mathbf{x})$ for any observed \mathbf{x} , i.e.

$$p_{ heta}(\mathbf{x}) pprox p_{\mathsf{d}}(\mathbf{x})$$

4. We wish $p_{\theta}(\mathbf{x})$ to be sufficiently flexible to be able to adapt to the data for obtaining sufficiently accurate model and to be able to incorporate prior knowledge.

Credit: Aditya Grover Hamid Beigy (Sharif University of Technology)

٢

- 1. The most common criterion for probabilistic models is maximum log-likelihood.
- 2. Maximization of the log-likelihood criterion is equivalent to minimization of a KL divergence between the data and model distributions.
- 3. We attempt to find the parameters θ that maximize the sum of the log-probabilities.

$$heta = rg\max_{ heta} \log \, p_{ heta}(D) = rg\max_{ heta} \sum_{i=1}^n \log \, p_{ heta}(\mathbf{x}_i)$$

- 4. We can efficiently compute gradients of this objective function.
- 5. We can use such gradients to iteratively hill-climb to a local optimum of the the objective function.
- If we compute such gradients using all data points, ∇_θ log p_θ(D), then this is known as batch gradient descent.
- 7. Computation of this derivative is an expensive operation for large dataset.

۲

- 1. A more efficient method for optimization is stochastic gradient descent(SGD).
- 2. The SGD uses randomly drawn mini-batches of data $B \subseteq D$ of size n_B .
- 3. With mini-batches, we can form an unbiased estimator of the log-likelihood as

$$\frac{1}{n}\log p_{\theta}(D) \approx \frac{1}{n_B}\log p_{\theta}(B) = \frac{1}{n_B}\sum_{\mathbf{x}\in B}\log p_{\theta}(\mathbf{x})$$

- 4. Symbol \approx means that one of the two sides is an unbiased estimator of the other side.
- 5. The unbiased estimator $\frac{1}{n_B} \log p_{\theta}(B)$ is differentiable, yielding the unbiased stochastic gradients:

$$\frac{1}{n} \nabla_{\theta} \log p_{\theta}(D) \approx \frac{1}{n_B} \nabla_{\theta} \log p_{\theta}(B) = \frac{1}{n_B} \sum_{\mathbf{x} \in B} \nabla_{\theta} \log p_{\theta}(\mathbf{x})$$

6. These gradients can be plugged into stochastic gradient-based optimizer.

Latent Variable Model

- 1. In economics, we are often interested in measuring things such as quality of life, moral, happiness, etc.
- 2. This things cannot be directly measured and are latent.
- 3. The idea is to link these latent variables to observed ones.
- 4. For example, assume that the **quality of life** can be inferred from some **linear combination** of some observed variables such as
 - wealth
 - employment
 - physical health
 - education
 - leisure time
- 5. Latent variables are part of model, but we cannot observe.
- 6. Latent variables are another way to represent the data.

Example (Generating images of handwritten digits)

1. Consider the following situations:

the left half	the right half	the character
left half of a 5	left half of a 0	???
left half of a 0	left half of a 4	???
left half of a 4	left half of a 1	similar to 4
left half of a 1	left half of a 9	???
left half of a 9	left half of a 1	similar to 9

- 2. Assume the model first choose a character to be generated before generating pixels.
- 3. This form of decision is formally called a latent variable.
 - Model randomly samples a digit value $z \in \{0, 1, \dots, 9\}$.
 - Generate an image based on z.

Latent variable model

- 1. Let $\mathbf{X} = (\mathbf{x}_1, \dots, \mathbf{x}_m)^{\top}$ be a dataset of samples $\mathbf{x}_i \in \mathcal{X}$, and $\mathbf{Z} = (\mathbf{z}_1, \dots, \mathbf{z}_m)^{\top}$ be the corresponding latent variables $\mathbf{z}_i \in \mathcal{Z}$.
- 2. We can easily sample **z** from its distribution p(z).
- 3. We have a family of deterministic functions $\mathbf{x} = g_{\theta}(\mathbf{z})$ parametrized by θ .

- 4. Function $g_{\theta}(.)$ is deterministic but z is random and θ is fixed, hence $g_{\theta}(z)$ is a random variable in \mathcal{X} .
- 5. We wish to optimize θ such that
 - we can sample z from p(z) and,
 - with high probability $g_{\theta}(z)$ will be like one sample in our dataset.

Estimating the log-likelihood

- 1. Let $\mathbf{X} = (\mathbf{x}_1, \dots, \mathbf{x}_n)^\top \in \mathbb{R}^{n \times d}$ be a dataset of samples $\mathbf{x}_i \in \mathbb{R}^d$, and $\mathbf{Z} = (\mathbf{z}_1, \dots, \mathbf{z}_n)^\top \in \mathbb{R}^{n \times K}$ be the corresponding latent variables $\mathbf{z}_i \in \mathbb{R}^K$.
- The goal of PCA is to learn a linear bidirectional mapping X ↔ Z such that as much information of X as possible is retained in Z.
- 3. Let the following linear mapping maps data from latent to observation space.

$$\hat{\mathbf{x}}_i = ar{\mathbf{x}} + \sum_{j=1}^K z_{ij} \mathbf{v}_j$$

where $\bar{\mathbf{x}}$ is data mean and $\mathbf{V} = (\mathbf{v}_1, \dots, \mathbf{v}_K)$ is an orthonormal basis.

4. The goal is to minimize the L_2 reconstruction loss wrt. Z and V.

$$\mathcal{L}(\mathbf{Z},\mathbf{V}) = \sum_{i=1}^{''} \|\hat{\mathbf{x}}_i - \mathbf{x}_i\|^2$$

- 1. Many probabilistic models have latent variables z.
- 2. In the case of unconditional modeling of observed variable **x**, the directed graphical model would then represent a joint distribution $p_{\theta}(\mathbf{x}, \mathbf{z})$.

1. Our aim is to maximize the probability of each **x** in the training set under the entire generative process using:

$$egin{aligned} p_{ heta}(\mathbf{x}) &= \int p_{ heta}(\mathbf{x}, \mathbf{z}) d\mathbf{z} \ &= \int p_{ heta}(\mathbf{x} \mid \mathbf{z}) \, p(\mathbf{z}) d\mathbf{z} \end{aligned}$$

- 2. Here, $g_{\theta}(z)$ was replaced by a distribution $p_{\theta}(x)$, which allows us to make the dependence of x on z explicit by using the law of total probability.
- 3. When $p_{\theta}(\mathbf{x} \mid \mathbf{z})$ is Gaussian,

$$p_{\theta}(\mathbf{x} \mid \mathbf{z}) = \mathcal{N}(g_{\theta}(\mathbf{z}), \sigma^2 \mathbf{I})$$

- 4. The mean iss $g_{\theta}(\mathbf{z})$ and covariance is the identity matrix I times some scalar σ (σ is a hyper-parameter).
- 5. This replacement is necessary to formalize the intuition that some z needs to result in samples that are merely like x.

- 1. By using Gaussian distribution, we can use optimization techniques such as GD to increase $p(\mathbf{x})$ by making $g_{\theta}(\mathbf{z})$ approach \mathbf{x} for some \mathbf{z} .
- 2. This is not possible if $p(\mathbf{x} | \mathbf{z})$ is a Dirac delta function.
- 3. $p(\mathbf{x} | \mathbf{z})$ is not required to be Gaussian.
- 4. When **x** is binary vector, then $p(\mathbf{x} | \mathbf{z})$ might be a Bernoulli parameterized by $g_{\theta}(\mathbf{z})$.
- 5. Important property is that $p(\mathbf{x} \mid \mathbf{z})$ can be computed, and is continuous in θ .
- 6. Latent variable model can be represented as the following PGM.

1. The marginal distribution over the observed variables, $p_{\theta}(\mathbf{x})$, is

$$egin{aligned} p_{ heta}(\mathbf{x}) &= \int p_{ heta}(\mathbf{x}, \mathbf{z}) d\mathbf{z} \ &= \int p_{ heta}(\mathbf{x} \mid \mathbf{z}) \, p(\mathbf{z}) d\mathbf{z} \ &= \mathbb{E}_{\mathbf{z} \sim \, p(\mathbf{z})}[\, p_{ heta}(\mathbf{x} \mid \mathbf{z})] \end{aligned}$$

- 2. This is called the marginal likelihood or model evidence when taken as a function of θ .
- 3. Assume that we cannot calculate the integral exactly.
- 4. The simplest approach would be to use the Monte Carlo approximation:

$$egin{aligned} p_{ heta}(\mathbf{x}) &= \int p_{ heta}(\mathbf{x} \mid \mathbf{z}) \, p(\mathbf{z}) d\mathbf{z} \ &= \mathbb{E}_{\mathbf{z} \sim \, p(\mathbf{z})}[\, p_{ heta}(\mathbf{x} \mid \mathbf{z})] \ &= rac{1}{n_B} \sum_k \, p_{ heta}(\mathbf{x} \mid \mathbf{z}_k) \end{aligned}$$

5. In the last line, we use samples from the prior over latents $z \sim p(z)$.

1. The marginal distribution over the observed variables, $p_{\theta}(\mathbf{x})$, is

$$p_{ heta}(\mathbf{x}) = \int p_{ heta}(\mathbf{x}, \mathbf{z}) d\mathbf{z}$$

- 2. Such an implicit distribution over **x** can be quite flexible.
 - If z is discrete and $p_{\theta}(\mathbf{x} \mid \mathbf{z})$ is a Gaussian distribution, then $p_{\theta}(\mathbf{x})$ is a mixture of Gaussian.
 - If z is continuous, then p_θ(x) can be seen as an infinite mixture, which are potentially more powerful than discrete mixture.

- $1. \ \mbox{Let}$ us consider the following situation
 - Continuous random variables only, i.e., $\mathbf{x} \in \mathbb{R}^d$ and $\mathbf{z} \in \mathbb{R}^K$.
 - The distribution of z is the standard Gaussian, i.e., $p(z) = \mathcal{N}(0, I)$.
 - The dependency between z and z is linear and we assume a Gaussian additive noise:

$$\mathbf{x} = \mathbf{W}\mathbf{z} + \mathbf{b} + \varepsilon$$

where $\varepsilon \sim \mathcal{N}(\mathbf{0}, \sigma^2 \mathbf{I})$

The property of the Gaussian distribution yields:

$$p(\mathbf{x} \mid \mathbf{z}) = \mathcal{N}(\mathbf{W}\mathbf{z} + \mathbf{b}, \sigma^2 \mathbf{I})$$

2. This model is known as the probabilistic PCA.

1. Then, we use linear combination of two normally-distributed random variables as

$$p(\mathbf{x}) = \int p(\mathbf{x} \mid \mathbf{z}) p(\mathbf{z}) d\mathbf{z}$$
$$= \int \mathcal{N}_{\mathbf{x}} (\mathbf{W}\mathbf{z} + \mathbf{b}, \sigma \mathbf{I}) \mathcal{N}_{\mathbf{z}} (0, \mathbf{I}) d\mathbf{z}$$
$$= \mathcal{N} (\mathbf{b}, \mathbf{W}\mathbf{W}^{\top} + \sigma^{2}\mathbf{I}).$$

- 2. We can calculate the logarithm of the (marginal) likelihood function $\ln p(\mathbf{x})$.
- 3. We can also calculate the true posterior over z.

$$p(\mathbf{z} \mid \mathbf{x}) = \mathcal{N}(\mathbf{M}^{-1}\mathbf{W}^{\top}(\mathbf{x} - \mu), \sigma^{-2}\mathbf{M})$$

where $\mathbf{M} = \mathbf{W}^{\top}\mathbf{W} + \sigma^{2}\mathbf{I}$.

- 1. Deep latent variable model (DLVM) is a latent variable model, $p_{\theta}(\mathbf{x}, \mathbf{z})$, whose distribution are parameterized by a neural network.
- 2. When the prior is Gaussian, the model is called deep latent Gaussian model (DLGM).
- 3. One advantage of DLVM is that even when each factor in the directed model is relatively simple, the marginal distribution, $p_{\theta}(\mathbf{x})$, can be very complex.
- 4. This makes DLVMs attractive for approximating complicated underlying distribution $p_d(x)$.
- 5. Perhaps the simplest and the most common DLVM is specified as factorization with the following structure:

$$p_{\theta}(\mathbf{x}, \mathbf{z}) = p_{\theta}(\mathbf{x} \mid \mathbf{z}) p(\mathbf{z})$$

where p(z) and $p_{\theta}(x \mid z)$ are specified.

Maximum Likelihood Learning

- 1. The main objective of DGMs is approximating the distribution $p_d(\mathbf{x})$ using $p_{\theta}(\mathbf{x})$.
- 2. Let having a dataset $D = \{\mathbf{x}_1, \dots, \mathbf{x}_m\}$ of i.i.d. and fully-observed samples.
- 3. We maximize the probability of observing the data with respect to the parameters θ .
- 4. The maximum likelihood fit is

$$heta = rg\max_{ heta} rac{1}{m} \sum_{i=1}^m \log \ p_{ heta}(\mathbf{x}_i)$$

5. In latent variable model, we have

$$p_{ heta}(\mathbf{x}) = \int \, p_{ heta}(\mathbf{x} \mid \mathbf{z}) \, p(\mathbf{z}) d\mathbf{z}$$

6. The maximum likelihood fit is

$$heta = rg \max_{ heta} rac{1}{n} \sum_{i=1}^{n} \log \left(\int p_{ heta}(\mathbf{x} \mid \mathbf{z}) p(\mathbf{z}) d\mathbf{z}
ight)$$

7. The main difficulty of maximum likelihood learning in DLVMs is that the marginal probability of data under the model is typically **intractable**.

Minimizing KL divergence

$$\begin{aligned} \arg\min_{\theta} \mathsf{D}_{\mathsf{KL}}(p_{\mathsf{d}}(\mathsf{x}) \mid\mid p_{\theta}(\mathsf{x})) &= \arg\min_{\theta} \mathbb{E}_{\mathsf{x} \sim p_{\mathsf{d}}(\mathsf{x})} \left[\log \frac{p_{\mathsf{d}}(\mathsf{x})}{p_{\theta}(\mathsf{x})} \right] \\ &= \arg\min_{\theta} \int p_{\mathsf{d}}(\mathsf{x}) \log \frac{p_{\mathsf{d}}(\mathsf{x})}{p_{\theta}(\mathsf{x})} d\mathsf{x} \\ &= \arg\min_{\theta} \underbrace{\int p_{\mathsf{d}}(\mathsf{x}) \log p_{\mathsf{d}}(\mathsf{x}) d\mathsf{x}}_{\mathsf{Constant term w.r.t } \theta} - \int p_{\mathsf{d}}(\mathsf{x}) \log p_{\theta}(\mathsf{x}) d\mathsf{x} \\ &= \arg\max_{\theta} \int p_{\mathsf{d}}(\mathsf{x}) \log p_{\theta}(\mathsf{x}) d\mathsf{x} \end{aligned}$$

Hence, minimizing KL divergence is equivalent to maximizing the likelihood.

Credit: Kaiming He Hamid Beigy (Sharif University of Technology)

1. We want to maximize $\log p_{\theta}(\mathbf{x})$ with

$$egin{aligned} p_{ heta}(\mathbf{x}) &= \int p_{ heta}(\mathbf{x}, \mathbf{z}) d\mathbf{z} \ &= \int p_{ heta}(\mathbf{x} \mid \mathbf{z}) \, p(\mathbf{z}) d\mathbf{z} \end{aligned}$$

- 2. There are two sets of unknown: **optimizing for** θ and **can not control** p(z).
- 3. The intractability is due to not having not an analytic solution or efficient estimator.
- 4. Hence, we cannot differentiate it w.r.t θ and optimize it as in fully observable models.
- 5. The intractability of $p_{\theta}(\mathbf{x})$ is related to the intractability of posterior $p_{\theta}(\mathbf{x} \mid \mathbf{z})$.
- 6. Since $p_{\theta}(\mathbf{x}, \mathbf{z})$ is efficient to compute, if $p_{\theta}(\mathbf{x})$ is tractable then $p_{\theta}(\mathbf{x} | \mathbf{z})$ is tractable and vice versa.

$$p_{ heta}(\mathsf{x} \mid \mathsf{z}) = rac{p_{ heta}(\mathsf{x},\mathsf{z})}{p_{ heta}(\mathsf{x})}$$

7. Solution: Introduce a controllable distribution q(z)

$$\log p_{\theta}(\mathbf{x}) = \int q(\mathbf{z}) \log p_{\theta}(\mathbf{x}) d\mathbf{z}$$
Rewrite using latent \mathbf{z}

$$= \int q(\mathbf{z}) \log \left(\frac{p_{\theta}(\mathbf{x} \mid \mathbf{z}) p_{\theta}(\mathbf{z})}{p_{\theta}(\mathbf{z} \mid \mathbf{x})} \right) d\mathbf{z}$$
Using Bayes rule
$$= \int q(\mathbf{z}) \log \left(\frac{p_{\theta}(\mathbf{x} \mid \mathbf{z}) p_{\theta}(\mathbf{z})}{p_{\theta}(\mathbf{z} \mid \mathbf{x})} \frac{q(\mathbf{z})}{q(\mathbf{z})} \right) d\mathbf{z}$$

$$= \int q(\mathbf{z}) \left(\log p_{\theta}(\mathbf{x} \mid \mathbf{z}) + \log \frac{p_{\theta}(\mathbf{z})}{q(\mathbf{z})} + \log \frac{q(\mathbf{z})}{p_{\theta}(\mathbf{z} \mid \mathbf{x})} \right) d\mathbf{z}$$

$$= \underbrace{\mathbb{E}_{\mathbf{z} \sim q(\mathbf{z})} [\log p_{\theta}(\mathbf{x} \mid \mathbf{z})]}_{\text{tractable}} - \underbrace{\mathbb{D}_{KL}(q(\mathbf{z}) \mid p_{\theta}(\mathbf{z} \mid \mathbf{x}))}_{\text{intractable}}$$
Evidence lower bound (ELBO)
$$+ \underbrace{\mathbb{D}_{KL}(q(\mathbf{z}) \mid p_{\theta}(\mathbf{z} \mid \mathbf{x}))}_{\text{intractable}}$$

This equation holds for any distribution q(z).

Hence, $\log p_{\theta}(\mathbf{x})$ becomes intractable!

- 1. How to overcome this problem?
- 2. Solution:
 - Parametrize q(z) by $q_{\phi}(z)$.
 - Let $p_{\theta}(z)$ be a simple known prior p(z).
- 3. Now maximize ELBO (variational lower bound) or equivalently minimize the following objective function.

$$\mathcal{L}(\theta, \phi) = \underbrace{-\mathbb{E}_{z \sim q_{\phi}(z)}[\log p_{\theta}(\mathbf{x} \mid \mathbf{z})]}_{\text{Reconstruction loss}} + \underbrace{\mathsf{D}_{\mathcal{K}L}(q_{\phi}(\mathbf{z}) \mid\mid p(\mathbf{z}))}_{\text{Regularization loss}}$$

4. The KL divergence is known as the variational gap.

5. How to maximize ELBO?

- 1. The problem is how to estimate $\log q(z | x)$ in which the posterior distribution is different for each data point x. This means that we need to learn different variational parameters ϕ for each data point x.
- 2. To overcome this issue, we use amortized variational inference.
- 3. In amortized variational inference, we train an external neural network to predict the variational parameters instead of optimizing ELBO per data point.
- 4. This network is called the inference network and from now on, ϕ parameters will refer to the inference network weights.
- 5. The main model (decoder network) and the inference network are trained simultaneously by maximizing ELBO with respect to both θ and ϕ .
- 6. Once we train the inference network, we can compute the variational posterior for a new data point by simply feeding the data point to the network.

- 1. We need to maximize ELBO with respect to both the parameters.
- 2. Variational autoencoder has the following architecture.

3. Example

Encoder

4

- $p(\mathbf{z}) = \mathcal{N}(\mathbf{0}, \mathbf{I})$
- $q_{\phi}(\mathbf{z} \mid \mathbf{x}) = \mathcal{N}(\mu_e, \sigma_e)$
- $f_{\phi}(\mathbf{x}) \rightarrow (\mu_e, \sigma_e)$

- Decoder
 - $p_{\theta}(\mathbf{x} \mid \mathbf{z}) = \mathcal{N}(g_{\theta}(\mathbf{z}), \sigma_d \mathbf{I})$
 - log $p_{ heta}(\mathbf{x} \mid \mathbf{z}) = rac{1}{2\sigma_d} \|\mathbf{x} g_{ heta}(\mathbf{z})\|^2 + \textit{const}$

Hence, loss becomes:

$$\mathcal{L}(\theta, \phi) = \underbrace{-\mathbb{E}_{\mathbf{z} \sim q_{\phi}(\mathbf{z} \mid \mathbf{x})} \left[\frac{1}{2\sigma_{d}} \|\mathbf{x} - g_{\theta}(\mathbf{z})\|^{2} \right]}_{\text{Reconstruction loss}} + \underbrace{\mathbb{D}_{KL}(\mathcal{N}(\mu_{e}, \sigma_{e}) \mid\mid \mathcal{N}(0, \mathbf{I}))}_{\text{Regularization loss}}$$

Hamid Beigy (Sharif University of Technology)

Example

1. Let $\mathbf{x} \sim \mathcal{N}(\mu, \sigma^2)$ and $\mathbf{z} \sim \mathcal{N}(0, 1)$. Now consider the following VAE:

where

$$\mathbf{z} = encode(\mathbf{x}) = a\mathbf{x} + b \qquad \qquad \phi = \{a, b\}$$
$$\mathbf{x} = decode(\mathbf{z}) = c\mathbf{z} + d \qquad \qquad \theta = \{c, d\}$$

2. Consider the following proxy distributions:

$$\begin{aligned} q_{\phi}(\mathbf{z} \mid \mathbf{x}) &= \mathcal{N}(a\mathbf{x} + b, 1) \\ p_{\theta}(\mathbf{x} \mid \mathbf{z}) &= \mathcal{N}(c\mathbf{z} + d, c) \end{aligned}$$

3. This problem has a trivial solution, find it.

Example

1. Consider the following proxy distributions of the previous example:

 $egin{aligned} q_{\phi}(\mathbf{z} \mid \mathbf{x}) &= \mathcal{N}(a\mathbf{x}+b,1) \ p_{ heta}(\mathbf{x} \mid \mathbf{z}) &= \mathcal{N}(c\mathbf{z}+d,c) \end{aligned}$

2. To determine ϕ , we need to maximize the regularization term

 $\mathsf{D}_{\mathcal{KL}}(q_{\phi}(\mathsf{z} \mid \mathsf{x}) \mid\mid p(\mathsf{z})) = \mathsf{D}_{\mathcal{KL}}(\mathcal{N}(\mathsf{a}\mathsf{x} + b, 1) \mid\mid \mathcal{N}(0, 1))$

Since E[x] = μ and var[x] = σ², the KL-divergence is minimized when a = 1/σ, b = -μ/σ.
 To determine θ, we need to maximize the reconstruction term:

$$\mathbb{E}_{q_{\phi}(\mathsf{z} \,|\, \mathsf{x})}[\log \, p_{\theta}(\mathsf{x} \mid \mathsf{z})] = \, \mathbb{E}_{q_{\phi}(\mathsf{z} \mid \mathsf{x})} \bigg[- \frac{(c\mathsf{z} + d - \mu)^2}{2c^2} \bigg]$$

5. Since $\mathbb{E}[\mathbf{z}] = 0$ and $\operatorname{var}[\mathbf{x}] = 1$, the term is maximized when $c = \sigma$ and $d = \mu$. 6. The encoder and decoder parameters are

$$\mathbf{z} = encode(\mathbf{x}) = \frac{\mathbf{x} - \mu}{\sigma}$$
$$\mathbf{x} = decode(\mathbf{z}) = a\mathbf{z} + \mu$$

1. Training

2. Inference

1. We need to maximize ELBO with respect to both the model parameters. This means that we need to compute the gradients of:

$$\mathcal{L}(heta, \phi) = \mathbb{E}_{q_{\phi}(\mathsf{z} \mid \mathsf{x})} igg[\log rac{p_{ heta}(\mathsf{x}, \mathsf{z})}{q_{\phi}(\mathsf{z} \mid \mathsf{x})} igg]$$

2. Unbiased gradients of the ELBO with respect to θ are:

$$egin{aligned}
abla_{ heta} \mathcal{L}(heta, \phi)(\mathbf{x}) &=
abla_{q_{\phi}(\mathbf{z} \mid \mathbf{x})} [\log p_{ heta}(\mathbf{x}, \mathbf{z}) - \log q_{\phi}(\mathbf{z} \mid \mathbf{x})] \ &= \mathbb{E}_{q_{\phi}(\mathbf{z} \mid \mathbf{x})} [
abla_{ heta}(\log p_{ heta}(\mathbf{x}, \mathbf{z}) - \log q_{\phi}(\mathbf{z} \mid \mathbf{x}))] \ &pprox
abla_{ heta}(\log p_{ heta}(\mathbf{x}, \mathbf{z}) - \log q_{\phi}(\mathbf{z} \mid \mathbf{x})) \ &=
abla_{ heta} \log p_{ heta}(\mathbf{x}, \mathbf{z}) \end{aligned}$$

- 3. Although exact gradient calculation with respect to the model parameters is possible, a much better approach is to use Monte Carlo sampling.
- 4. We generate a handful of samples for the variational posterior and average them. That way we estimate the gradients instead of calculating them in a closed form.

$$\nabla_{\theta} \mathcal{L}(\theta, \phi) = \frac{1}{K} \sum_{k=1}^{K} \nabla_{\theta} \log p_{\theta}(\mathbf{x}, \mathbf{z}^{k}) \qquad \text{where } \mathbf{z}^{k} \sim q_{\phi}(\mathbf{z} \mid \mathbf{x})$$

5. Then, use back-propagation algorithm to update the model parameters. Hamid Beigy (Sharif University of Technology)

1. Unbiased gradients with respect to the variational parameters ϕ are more difficult to obtain, since the ELBO's expectation is taken with respect to the distribution $q_{\phi}(\mathbf{z} \mid \mathbf{x})$, which is a function ϕ :

$$\begin{split} \mathcal{L}(\theta, \phi) &= \mathbb{E}_{q_{\phi}(\mathbf{z} \mid \mathbf{x})} \bigg[\log \frac{p_{\theta}(\mathbf{x}, \mathbf{z})}{q_{\phi}(\mathbf{z} \mid \mathbf{x})} \bigg] \\ \nabla_{\phi} \, \mathcal{L}(\theta, \phi) &= \nabla_{\theta} \, \mathbb{E}_{q_{\phi}(\mathbf{z} \mid \mathbf{x})} [\log \, p_{\theta}(\mathbf{x}, \mathbf{z}) - \log \, q_{\phi}(\mathbf{z} \mid \mathbf{x})] \\ &\neq \mathbb{E}_{q_{\phi}(\mathbf{z} \mid \mathbf{x})} [\nabla_{\phi}(\log \, p_{\theta}(\mathbf{x}, \mathbf{z}) - \log \, q_{\phi}(\mathbf{z} \mid \mathbf{x}))] \end{split}$$

- 2. Why cannot we to obtain the above gradient?
- 3. If we can calculate such a gradient, we can use back-propagation algorithm to update the variational parameters.
- 1. Problem is transforming a sample from a fixed, known distribution to a sample from $q_{\phi}(\mathbf{z} \mid \mathbf{x})$.
- 2. If we consider the Gaussian distribution, we can express **z** with respect to a fixed $\epsilon \sim \mathcal{N}(0, I)$.

$$\mathbf{z} = \mu + \sigma \epsilon$$
 where $\epsilon \sim \mathcal{N}(0, I)$

3. The ϵ term introduces the stochastic part and it is not involved in the training process.

Gradient of expectation under change of variable

1. Given change of variable, expectations can be rewritten in terms of ϵ :

$$\mathbb{E}_{q_{\phi}(\mathsf{z} \mid \mathsf{x})}[f(\mathsf{z})] = \mathbb{E}_{p(\epsilon)}[f(\mathsf{z})]$$

2. Then, the expectation and gradient operators become commutative, and we can form a simple Monte Carlo estimator

- 1. Under the reparameterization, we can replace an expectation with respect to $q_{\phi}(\mathbf{z} \mid \mathbf{x})$ with one with respect to $p(\epsilon)$.
- 2. The ELBO can be rewritten as:

$$egin{aligned} \mathcal{L}(heta,\phi)(\mathbf{x}) &= \mathbb{E}_{q_{\phi}(\mathbf{z}\,|\,\mathbf{x})}[\log \,p_{ heta}(\mathbf{x},\mathbf{z}) - \log \,q_{\phi}(\mathbf{z}\,|\,\mathbf{x})] \ &= \mathbb{E}_{\,
ho(\epsilon)}[\log \,
ho_{ heta}(\mathbf{x},\mathbf{z}) - \log \,q_{\phi}(\mathbf{z}\,|\,\mathbf{x})] \end{aligned}$$

3. As a result we can form a simple Monte Carlo estimator $\widehat{\mathcal{L}}(\theta, \phi)(\mathbf{x})$ of the individual data ELBO, where we use a single noise sample ϵ from $p(\epsilon)$:

$$\widehat{\mathcal{L}}(heta, \phi)(\mathbf{x}) = \log p_{ heta}(\mathbf{x}, \mathbf{z}) - \log q_{\phi}(\mathbf{z} \mid \mathbf{x})$$

4. **HW:** Show that this gradient is an unbiased estimator of the exact single data ELBO gradient.

Results of VAE

- 1. Consider the first and third rows of the following figure:
 - The first line is deterministic autoencoder
 - The third row is VAE

2. Despite success on small scale datasets, when applied to more complex datasets such as natural images, samples tend to be unrealistic and blurry.

1. Consider an autoencoder

2. The goal of autoencoder is to minimize reconstruction loss given by

$$\min_{\theta,\phi}\{\|\mathbf{X}-\widehat{\mathbf{X}}\|^2\}$$

3. This means that a good intermediate representation not only can capture latent variables, but also benefits a full decompression process.

Variants of VAE

- 1. How can we interpret the latent vector of VAE?
- 2. A model trained on photos of human faces might capture
 - gentle,
 - skin color,
 - hair color,
 - hair length,
 - emotion,
 - glasses (if any),
 - many other relatively independent factors.
- 3. Such a disentangled representation is very beneficial to facial image generation.

Beta-VAE

- 1. Beta-VAE is a modification of VAE with a special emphasis to discover disentangled latent factors (Higgins et al. 2017).
- In β-VAE, we want to maximize the probability of generating real data, while keeping the distance between the real and estimated posterior distributions small (less than a small constant δ):

$$\max_{\phi,\theta} \mathbb{E}_{\mathbf{x} \sim p_{\mathsf{d}}(\mathbf{x})} \left[\mathbb{E}_{\mathbf{z} \sim q_{\phi}(\mathbf{z} \mid \mathbf{x})} \log p_{\theta}(\mathbf{x} \mid \mathbf{z}) \right] \text{ subject to } \qquad \mathsf{D}_{\mathit{KL}}(q_{\phi}(\mathbf{z} \mid \mathbf{x}) \mid\mid p(\mathbf{z})) \leq \delta$$

- 3. We can rewrite it as a Lagrangian with a Lagrangian multiplier β under the KKT condition.
- 4. The above optimization problem with only one inequality constraint is equivalent to maximizing $\mathcal{F}(\phi, \theta, \beta)$ as :

$$\begin{aligned} \mathcal{F}(\phi, \theta, \beta) &= \mathbb{E}_{\mathsf{z} \sim q_{\phi}(\mathsf{z} \mid \mathsf{x})} \log p_{\theta}(\mathsf{x} \mid \mathsf{z}) - \beta(\mathsf{D}_{\mathsf{KL}}(q_{\phi}(\mathsf{z} \mid \mathsf{x}) \mid\mid p(\mathsf{z})) - \delta) \\ &= \mathbb{E}_{\mathsf{z} \sim q_{\phi}(\mathsf{z} \mid \mathsf{x})} \log p_{\theta}(\mathsf{x} \mid \mathsf{z}) - \beta \mathsf{D}_{\mathsf{KL}}(q_{\phi}(\mathsf{z} \mid \mathsf{x}) \mid\mid p(\mathsf{z})) + \beta\delta \\ &\geq \mathbb{E}_{\mathsf{z} \sim q_{\phi}(\mathsf{z} \mid \mathsf{x})} \log p_{\theta}(\mathsf{x} \mid \mathsf{z}) - \beta \mathsf{D}_{\mathsf{KL}}(q_{\phi}(\mathsf{z} \mid \mathsf{x}) \mid\mid p(\mathsf{z})) \qquad \text{Since } \beta, \delta \ge 0 \end{aligned}$$

1. Hence, the loss function of beta-VAE is defined as

$$\mathcal{L}_{\mathsf{BETA}}(\phi, \theta, \beta) = -\mathbb{E}_{\mathsf{z} \sim q_{\phi}(\mathsf{z} \mid \mathsf{x})} \log p_{\theta}(\mathsf{x} \mid \mathsf{z}) + \beta \mathsf{D}_{\mathsf{KL}}(q_{\phi}(\mathsf{z} \mid \mathsf{x}) \mid\mid p(\mathsf{z}))$$

where the Lagrangian multiplier β is considered as a hyper-parameter.

- 2. Since $-\mathcal{L}_{BETA}(\phi, \theta, \beta)$ is the lower bound of the Lagrangian, minimizing the loss is equivalent to maximizing the Lagrangian.
- 3. Considering β ,
 - when $\beta = 1$, we have standard VAE, and
 - when $\beta > 1$, it applies a stronger constraint on the latent bottleneck and limits the representation capacity of z.
- 4. For some conditionally independent generative factors, keeping them disentangled is the most efficient representation.
- 5. Therefore a higher β encourages more efficient latent encoding and hence disentanglement.
- 6. Hence, a higher β may create a trade-off between reconstruction quality and the extent of disentanglement.

1. Consider Latent factors learnt by β -VAE on celebA data set.

2. This experiment shows that β -VAE discovers some factors in an unsupervised manner that encode skin colour, transition from an elderly male to younger female, and image saturation.

1. Consider the loss function of Beta-VAE

$$\mathcal{L}_{\mathsf{BETA}}(\phi, \theta, \beta) = -\mathbb{E}_{\mathsf{z} \sim q_{\phi}(\mathsf{z} \mid \mathsf{x})} \log p_{\theta}(\mathsf{x} \mid \mathsf{z}) + \beta \mathsf{D}_{\mathsf{KL}}(q_{\phi}(\mathsf{z} \mid \mathsf{x}) \mid\mid p(\mathsf{z}))$$

2. Assume that every pixel x_k is conditionally independent given z. Then, the first term becomes

$$\begin{split} \mathbb{E}_{\mathsf{z} \sim q_{\phi}(\mathsf{z} \mid \mathsf{x})} \log \, p_{\theta}(\mathsf{x} \mid \mathsf{z}) &= \mathbb{E}_{\mathsf{z} \sim q_{\phi}(\mathsf{z} \mid \mathsf{x})} \log \prod_{k} \, p_{\theta}(x_{k} \mid \mathsf{z}) \\ &= \mathbb{E}_{\mathsf{z} \sim q_{\phi}(\mathsf{z} \mid \mathsf{x})} \sum_{k} \log \, p_{\theta}(x_{k} \mid \mathsf{z}) \end{split}$$

3. Dividing both sides of $\mathcal{L}_{\text{BETA}}(\phi, \theta, \beta)$ by *n* produces

$$\mathcal{L}_{\mathsf{BETA}}(\phi,\theta,\beta) \approx -\mathbb{E}_{\mathsf{z}\sim q_{\phi}(\mathsf{z}\,|\,\mathsf{x})}[\mathbb{E}_{k}[\log p_{\theta}(\mathsf{x}_{k}\mid\mathsf{z})]] + \frac{\beta}{n} \mathsf{D}_{\mathsf{KL}}(q_{\phi}(\mathsf{z}\mid\mathsf{x})\mid\mid p_{\theta}(\mathsf{z}))$$
(1)

 \sim

- 4. We design β -VAE to learn conditionally independent factors of variation in the data.
- 5. Hence we assume conditional independence of every latent z_m given x.

Hamid Beigy (Sharif University of Technology)

Beta-VAE

1. Since our prior p(z) is an isotropic unit Gaussian, we can re-write the second term of $\mathcal{L}_{\text{BETA}}(\phi, \theta, \beta)$ as:

$$\begin{aligned} \mathsf{D}_{\mathsf{KL}}(q_{\phi}(\mathbf{z} \mid \mathbf{x}) \mid\mid p(\mathbf{z})) &= \int_{\mathbf{z}} q_{\phi}(\mathbf{z} \mid \mathbf{x}) \log \frac{q_{\phi}(\mathbf{z} \mid \mathbf{x})}{p(\mathbf{z})} \\ &= \sum_{k} \int_{z_{k}} q_{\phi}(z_{k} \mid \mathbf{x}) \log \frac{q_{\phi}(z_{k} \mid \mathbf{x})}{p(z_{k})} \\ &= \mathsf{K} \, \mathbb{E}_{k} \Big[\int_{z_{k}} q_{\phi}(z_{k} \mid \mathbf{x}) \log \frac{q_{\phi}(z_{k} \mid \mathbf{x})}{p(z_{k})} \Big] \end{aligned}$$

where K is dimensionality of latent variable

2. Combining the above terms produces

$$\mathcal{L}_{\mathsf{BETA}}(\phi,\theta,\beta) \approx -\mathbb{E}_{\mathbf{z}\sim q_{\phi}(\mathbf{z}\mid\mathbf{x})} [\mathbb{E}_{k}[\log p_{\theta}(x_{k}\mid\mathbf{z})]] + \frac{K\beta}{n} \mathbb{E}_{k} \left[\int_{z_{k}} q_{\phi}(z_{k}\mid\mathbf{x}) \log \frac{q_{\phi}(z_{k}\mid\mathbf{x})}{p(z_{k})} \right]$$
(2)

3. Hence, $\beta_{norm} = \frac{K\beta}{n}$, which is equivalent to optimising the original β -VAE.

Hamid Beigy (Sharif University of Technology)

1. In discrete latent variable model, the latent variables are **discrete**.

- 2. The VQ-VAE model uses discrete latent variables (Oord, Vinyals, and Kavukcuoglu 2017).
- 3. This discrete nature allows for more interpretable and sometimes more robust representations.
- 4. Discrete representations may be a more natural fit for problems like language, speech, reasoning.
- 5. The VQ-VAE model combines benefits of VAEs with vector quantization.

- 1. Key Components of VQ-VAE
 - Encoder: Maps the input to a continuous latent space.
 - Codebook (Embedding Space): A set of discrete latent embeddings (vectors).
 - Quantizer: Maps the continuous latent vectors to the nearest discrete embedding from the codebook.
 - Decoder: Reconstructs the input from the quantized latent vectors.
- 2. Vector quantisation is a method to map *d*-dimensional vectors into a finite set of **code** vectors.
- 3. Let E be the latent embedding space, codebook, in VQ-VAE.
- 4. An individual embedding vector is \mathbf{e}_i (for i = 1..., K).
- 5. These vectors are learned during training and serve as the possible latent representations for the input data.

1. The encoder outputs $E(x) = z_e$ goes through a nearest-neighbor lookup to match to one of K embedding vectors.

$$\mathbf{z}_q(\mathbf{x}) = \mathsf{Quantize}(E(\mathbf{x})) = \mathbf{e}_k$$
 where $k = \arg\min_i ||\mathbf{x} - \mathbf{e}_i||_2$

2. Then, this matched code vector becomes the input for the decoder D(.).

- 1. The discrete latent variables can have different shapes in different applications; for example,
 - 1D for speech,
 - 2D for image, and
 - 3D for video
- 2. Hence, the VQ-VAE becomes .

1. Here, we have

$$q(\mathbf{z} = \mathbf{e}_k \mid \mathbf{x}) = \begin{cases} 1 & \text{if } k = \arg\min_i \|\mathbf{z}_e(\mathbf{x}) - \mathbf{e}_i\|_2 \\ 0 & \text{otherwise} \end{cases}$$

- 2. Since *argmin* is non-differentiable on a discrete space, the gradients \mathcal{L}_{VQ-VAE} from decoder input \mathbf{z}_q is copied to the encoder output \mathbf{z}_e (called straight-through gradient estimation).
- 3. Loss function for VQ-VAE is

$$\mathcal{L}_{VQ-VAE} = \underbrace{\|\mathbf{x} - D(\mathbf{e}_k)\|_2^2}_{\text{reconstruction loss}} + \underbrace{\|\text{sg}[E(\mathbf{x})] - \mathbf{e}_k\|_2^2}_{\text{VQ loss}} + \underbrace{\beta \|\mathbf{x} - \text{sg}[\mathbf{e}_k]\|_2^2}_{\text{commitment loss}}$$

where sg[.] is the stop gradient operator.

4. The embedding vectors in the codebook is updated through EMA (exponential moving average).

Vector Quantized-Variational AutoEncoder

1. Given a code vector \mathbf{e}_i , say we have n_i encoder output vectors, $\{\mathbf{z}_{i,j}\}_{j=1}^{n_i}$, that are quantized to \mathbf{e}_i

$$N_i^{(t)} = \gamma N_i^{(t-1)} + (1-\gamma) n_i^{(t)}$$
$$\mathbf{m}_i^{(t)} = \gamma \mathbf{m}_i^{(t-1)} + (1-\gamma) \sum_{j=1}^{n_i^{(t)}} \mathbf{z}_{i,j}^{(t)}$$
$$\mathbf{e}_i^{(t)} = \mathbf{m}_i^{(t)} / N_i^{(t)}$$

where (t) refers to batch sequence in time. N_i and \mathbf{m}_i are accumulated vector count and volume, respectively.

2. Left: ImageNet 128 × 128 × 3 images. Right: reconstructions from a VQ-VAE with a $32 \times 32 \times 1$ and latent space, with K = 512.

Hamid Beigy (Sharif University of Technology)

٢

Advantages of VQ-VAE

- 1. **Discrete Latent Space:** Produces discrete and interpretable latent representations, which can be beneficial for tasks such as image generation and classification.
- 2. **Improved Quality:** Often generates sharper and more realistic images compared to traditional VAEs.
- 3. Scalability: Can be scaled to high-dimensional data and larger datasets.

Applications of VQ-VAE

- 1. Image Generation: Generating high-quality images from latent representations..
- 2. Speech Synthesis: Converting text to speech by learning discrete speech representations..
- 3. **Data Compression:** Efficiently compressing data by learning compact latent representations..

Variants of VAE

Hierarchical VAE

1. Some researchers have proposed hierarchical VAEs (Sønderby et al. 2016).

$$p(\mathbf{x} \mid \mathbf{z}) = p(\mathbf{x} \mid \mathbf{z}_1) \prod_{k=1}^{L-1} p(\mathbf{z}_k \mid \mathbf{z}_{k+1})$$

2. There are some VAEs are effectively stacked on top of each other

- 1. There are two potential advantages of using hierarchical VAEs:
 - They could improve the Evidence Lower Bound (ELBO) and decrease reconstruction error.
 - The stack of latent variables z_k might learn a feature hierarchy similar to those learned by convolutional neural networks.
- 2. It is shown that that if the purpose is to learn structured, hierarchical features, using a hierarchical VAE has limitations (Zhao, Song, and Ermon 2017).
- 3. Homework: Drive variational inference for hierarchical VAE.
- 4. Homework: Read (Sønderby et al. 2016) and (Zhao, Song, and Ermon 2017).

Variants of VAE

Conditional VAE

1. In a conditional VAE, we have (Kingma, Mohamed, et al. 2014)

- a conditional generative model p_θ(z, x | c) on latent variables z, data x, conditioned on c and parameterized by θ and
- a conditional inference network $q_{\phi}(\mathbf{z} \mid \mathbf{x}, \mathbf{c})$ conditioned on **c** and parameterized by ϕ .
- 2. Given a true conditional data distribution $p(\mathbf{x} \mid \mathbf{c})$ for all \mathbf{c} , we want to learn (θ, ϕ) s.t.
 - $p_{\theta}(\mathbf{x} \mid \mathbf{c})$ approximates $p(\mathbf{x} \mid \mathbf{c})$ for all \mathbf{c} and
 - $q_{\phi}(\mathbf{z} \mid \mathbf{x}, \mathbf{c})$ approximates $p(\mathbf{z} \mid \mathbf{x}, \mathbf{c})$ for all \mathbf{x}, \mathbf{c} .

1. The inference process, in which latent representation is extracted from actual samples, is $q_{\phi}(\mathbf{x}, \mathbf{z}, \mathbf{c}) = q_{\phi}(\mathbf{z} \mid \mathbf{x}, \mathbf{c}) q(\mathbf{x}, \mathbf{c}).$

ground truth

2. To obtain a sample (z, x, c) from this joint we simply perform the following:

$$egin{aligned} \mathsf{x},\mathsf{c} &\sim \ q(\mathsf{x},\mathsf{c}) \ & \mathsf{z} &\sim \ q_{\phi}(\mathsf{z} \mid \mathsf{x},\mathsf{c}) \end{aligned}$$

where

- $q(\mathbf{x}, \mathbf{c})$ is the ground truth data distribution,
- $q_{\phi}(\mathbf{z} \mid \mathbf{x}, \mathbf{c})$ is the learnable variational posterior.
- 3. The generative process, in which samples are generated, is

$$egin{aligned} \mathsf{z},\mathsf{c} &\sim \ p(\mathsf{z},\mathsf{c}) & \mathsf{prior} \ \mathsf{x} &\sim \ p_{ heta}(\mathsf{x} \mid \mathsf{z},\mathsf{c}) \end{aligned}$$

Hamid Beigy (Sharif University of Technology)

- 1. Since joint distribution for both processes are $p_{\theta}(\mathbf{x}, \mathbf{z}, \mathbf{c})$ and $q_{\phi}(\mathbf{x}, \mathbf{z}, \mathbf{c})$, we can derive their KL distribution.
- 2. Let $D_{KL}(q(.) \parallel p(.)) = D_{KL}(q_{\phi}(\mathbf{x}, \mathbf{z}, \mathbf{c}) \parallel p_{\theta}(\mathbf{x}, \mathbf{z}, \mathbf{c}))$. Thus, we have

$$\begin{aligned} \arg \max_{\theta,\phi} \{-\mathsf{D}_{\mathsf{KL}}(q(.) \mid\mid p(.))\} &= \mathbb{E}_{q_{\phi}(\mathsf{x},\mathsf{z},\mathsf{c})} \left[\log \frac{p_{\theta}(\mathsf{x},\mathsf{z},\mathsf{c})}{q_{\phi}(\mathsf{x},\mathsf{z},\mathsf{c},\mathsf{c})} \right] \\ &= \mathbb{E}_{q_{\phi}(\mathsf{z}\mid\mathsf{x},\mathsf{c})} \left[\log \frac{p_{\theta}(\mathsf{x}\mid\mathsf{z},\mathsf{c}) p(\mathsf{x},\mathsf{c})}{q_{\phi}(\mathsf{z}\mid\mathsf{x},\mathsf{c})} \right] - \mathbb{E}_{q(\mathsf{x},\mathsf{c})} [\log q(\mathsf{x},\mathsf{c})] \\ &= \mathbb{E}_{q_{\phi}(\mathsf{x},\mathsf{z},\mathsf{c})} \left[\log \frac{p_{\theta}(\mathsf{x}\mid\mathsf{z},\mathsf{c}) p(\mathsf{z},\mathsf{c})}{q_{\phi}(\mathsf{z}\mid\mathsf{x},\mathsf{c})} \right] - \operatorname{const.} \\ &= \mathbb{E}_{q_{\phi}(\mathsf{x},\mathsf{z},\mathsf{c})} [\log p_{\theta}(\mathsf{x}\mid\mathsf{z},\mathsf{c})] + \mathbb{E}_{q_{\phi}(\mathsf{z}\mid\mathsf{x},\mathsf{c})} \left[\log \frac{p(\mathsf{z},\mathsf{c})}{q_{\phi}(\mathsf{z}\mid\mathsf{x},\mathsf{c})} \right] \\ &- \operatorname{const.} \\ &= \mathbb{E}_{q_{\phi}(\mathsf{z},\mathsf{x},\mathsf{c})} [\log p_{\theta}(\mathsf{x}\mid\mathsf{z},\mathsf{c})] - \mathsf{D}_{\mathsf{KL}}(q_{\phi}(\mathsf{z}\mid\mathsf{x},\mathsf{c}) \mid\mid p(\mathsf{z},\mathsf{c})) \end{aligned}$$

- 3. This gives the typical formulation of the ELBO which we see in most VAE papers.
- 4. Now, we must specify $p(\mathbf{z}, \mathbf{c})$. We have two cases
 - When they are independent
 - When they are dependent

- 1. When z and c are independent, we have p(z, c) = p(z) p(c).
- 2. This means that the joint distribution of the generative process factorises into:

$$p_{ heta}(\mathbf{x},\mathbf{z},\mathbf{c})=\,p_{ heta}(\mathbf{x}\mid\mathbf{z},\mathbf{c})\,p(\mathbf{z})\,p(\mathbf{c})$$

3. This leads us to the following ELBO

$$\begin{aligned} -\operatorname{D}_{\mathsf{KL}}(q_{\phi}(\mathbf{x}, \mathbf{z}, \mathbf{c}) \mid\mid p_{\theta}(\mathbf{x}, \mathbf{z}, \mathbf{c})) &= \operatorname{\mathbb{E}}_{q_{\phi}(\mathbf{x}, \mathbf{z}, \mathbf{c})}[\log p_{\theta}(\mathbf{x} \mid \mathbf{z}, \mathbf{c})] \\ &+ \operatorname{\mathbb{E}}_{q_{\phi}(\mathbf{x}, \mathbf{z}, \mathbf{c})}\left[\log \frac{p(\mathbf{z})}{q_{\phi}(\mathbf{z} \mid \mathbf{x}, \mathbf{c})}\right] + \log p(\mathbf{c}) \\ &= \mathsf{likelihood} - \operatorname{D}_{\mathsf{KL}}(q_{\phi}(\mathbf{z} \mid \mathbf{x}, \mathbf{c}) \mid\mid p(\mathbf{z})) + \mathsf{constants} \end{aligned}$$

4. Here, $p(\mathbf{c})$ is prior for **c** but it falls out of the KL term since it is a constant.

- This factorization is useful to encode if we are seeking to learn disentangled representations.
- This would make for a very controllable generative process where we could arbitrarily mix and match style and content variables from different examples to create new ones.

Conditional VAE (When z and c are dependent)

- 1. In general z and c may not be independent, we have p(z, c) = p(z | c) p(c).
- 2. This means that the joint distribution of the generative process factorises into:

$$p_{\theta}(\mathbf{x}, \mathbf{z}, \mathbf{c}) = p_{\theta}(\mathbf{x} \mid \mathbf{z}, \mathbf{c}) p(\mathbf{z} \mid \mathbf{c}) p(\mathbf{c})$$

3. This leads us to the following ELBO

$$\begin{aligned} -\operatorname{D}_{\mathsf{KL}}(q_{\phi}(\mathbf{x}, \mathbf{z}, \mathbf{c}) \mid\mid p_{\theta}(\mathbf{x}, \mathbf{z}, \mathbf{c})) &= \operatorname{\mathbb{E}}_{q_{\phi}(\mathbf{x}, \mathbf{z}, \mathbf{c})}[\log p_{\theta}(\mathbf{x} \mid \mathbf{z}, \mathbf{c})] \\ &+ \operatorname{\mathbb{E}}_{q_{\phi}(\mathbf{x}, \mathbf{z}, \mathbf{c})}\left[\log \frac{p(\mathbf{z} \mid \mathbf{c})}{q_{\phi}(\mathbf{z} \mid \mathbf{x}, \mathbf{c})}\right] + \log p(\mathbf{c}) \\ &= \mathsf{likelihood} - \operatorname{D}_{\mathsf{KL}}(q_{\phi}(\mathbf{z} \mid \mathbf{x}, \mathbf{c}) \mid\mid p(\mathbf{z} \mid \mathbf{c})) + \mathsf{constants.} \end{aligned}$$

4. Here, $p(\mathbf{c})$ is prior for **c** but it falls out of the KL term since it is a constant.

1. By looking at both versions of the ELBO, we can write them as:

$$\begin{split} \min_{\theta,\phi} \{ - \mathbb{E}_{q_{\phi}(\mathbf{x},\mathbf{z},\mathbf{c})} [\log p_{\theta}(\mathbf{x} \mid \mathbf{z},\mathbf{c})] + \beta \mathsf{D}_{KL}(q_{\phi}(\mathbf{z} \mid \mathbf{x},\mathbf{c}) \mid\mid p(\mathbf{z} \mid \mathbf{c})) \} & \text{Dependent case} \\ \min_{\theta,\phi} \{ - \mathbb{E}_{q_{\phi}(\mathbf{x},\mathbf{z},\mathbf{c})} [\log p_{\theta}(\mathbf{x} \mid \mathbf{z},\mathbf{c})] + \beta \mathsf{D}_{KL}(q_{\phi}(\mathbf{z} \mid \mathbf{x},\mathbf{c}) \mid\mid p(\mathbf{z})) \} & \text{Independent case} \end{split}$$

- 2. The first equation is maximizing the likelihood of the data with respect to samples from the inference network.
- 3. In order for this to happen, z should encode as much information about x as possible through the variational posterior $q_{\phi}(z \mid x, c)$, which is our learned encoder.
- 4. The second term is working against the first, because it is enforcing that each per example variational posterior must be close to the prior distribution.
- 5. Since the prior is not a function of x, it implies that some information about x in the encoding pathway has to be lost.
- 6. **Homework:** Please above optimization functions from mutual information perspective, and describe what happens.
- 7. Homework: Please read (Rathakumar et al. 2023), (Guo et al. 2024) and (Harvey, Naderiparizi, and Wood 2022).
