This research concerns the calculation of the effective transport properties of multi-phase composite materials. The composite materials under investigation are composed of a periodic array of inclusions embedded in a matrix. The geometry of the inclusions taken into account are circular cylindrical, elliptical cylindrical and spherical. The inclusions can be solid or multiply coated. The method used for these studies is Rayleigh’s method. Highly accurate values for the lattice sums have been obtained using recently developed algorithms. A series of explicit formulations used to facilitate the calculation of the effective transport property of the systems under study are reported here.

The behavior of the systems as a function of the transport properties of the phases is inspected. For multi-phase composites with cylindrical inclusions highly an-isotropic behavior is observed.

The procedure for finding the equivalent systems of multi-coated systems with circular cylindrical inclusions, when the sum of the transport property of the layers is equal to zero, is studied. It is found that to construct the equivalent system in multi-coated systems, many layers should be modified. Furthermore, multi-coated systems with elliptical cylindrical and spherical inclusions do not have similar equivalent systems. The results are verified using a numerical simulation method.

The effect of interfacial resistance on the effective conductivity of multi-phase systems with circular cylindrical and spherical inclusions is studied, assuming that the interfacial resistance is concentrated on the surface of the inclusions. It is found that there is a specific condition in which the effect of one phase on multi-phase systems in the direction of calculation of the effective conductivity can be neglected. This condition may be estimated by $R \leq k - 1$, where $R$ and $k$ are the non-dimensional interfacial resistance and the relative conductivity of the neglected cylinders, respectively. The case $R = k - 1$ applies when the same relation exists between the interfacial resistance and conductivity of all types of cylinders.

Two resistor models are used for deriving the upper and lower bounds of the effective transport property. It is found that the physical behavior of these bounds can be different from the natural behavior of the systems.

Keywords: transport property, multi-phase, composite materials.

ACKNOWLEDGEMENTS

The present research was carried out from October 1999 to May 2003 in the Department of Energy and Environmental Technology at Lappeenranta University of Technology.

First of all, I would like to express my sincerest gratitude to my teacher and supervisor, Professor Pertti Sarkomaa, for all the valuable comments and support he provided during this study.

The pre-examiners of the dissertation, Professor Mujid Kazimi (Massachusetts Institute of Technology) and Professor Seppo Korpela (Ohio State University) deserve special thanks for their numerous corrections and insightful comments. I relied on Professor Jingfang Huang (University of North Carolina) for the section of the thesis on lattice sums, and I thank Professor Huang for his help. I would like to express my gratitude to Professor Piroz Zamankhan for his guidance and the many courses he taught me. I am also thankful for the kindness shown to me by Mr. Mahmood Khalighi.

I would like to express my warmest thanks to Dr. Mika Horttanainen and Professor Juha Kaikko for their great support and help. I held many discussions with Dr. Hooman Vahedi, Dr. Payman Jalali, Amir Shakib-Manesh and Parsa Zamankhan. I am grateful for their suggestions that were valuable to this thesis. I also wish to thank Mrs. Anne Jordan, Mrs. Päivi Friari, Panu Liikola and Antti Wemberg for the kind contributions they made during the different stages of this study.

I offer my thanks to all the staff in the Department of Energy and Environmental Technology. I owe special thanks to Mrs. Maisa Raatkainen, Mrs. Annikki Tuuva and Mrs. Jaana Mäkitalo. Last but definitely not least, I acknowledge my present and former friends in the department. In particular, I thank Veli-Matti Väärälä, Tero Tynjälä, Teemu Turunen, Jouni Ritvanen, Hossein Ghazanfari, Pekka Punnonen and Visa Poikolainen for creating a relaxed but professional atmosphere in the department, which has fostered a good research environment.

This thesis and the related papers have been proofread mostly by Amir Hassan and partially by Mrs. Sinikka Talonpoika, for which I offer my thanks.

Finally, I would like to dedicate this thesis to my parents and my brother and sister; to those people whose kindness has been pure.

1. INTRODUCTION

1.1 Composite materials: definition, classification and importance

There is no unique definition for composite materials [Schwartz, 1984], and different definitions are available; however, for our purposes, the term composite material refers to a system that consists of two or more distinct phases that are separated from each other by an interface. The phases are insoluble in each other. Composites usually have three parts; namely, a matrix (background), structural constituents and an interface. The matrix is a homogeneous material which surrounds the other phases and the interface is the boundary or surface between the phases. One way of classifying composites is according to the specification of the structural constituents. The structural constituent can take many forms such as particles, fibers, laminates, fillers, flakes or combinations of the above.

The above definition brings to mind many systems that are of clear and essential technological importance. Examples are wood, foam, oil-filled porous rocks, colloidal suspensions, emulsions, solid rocket propellant, concrete, reinforced materials, to name just a few. Therefore the study of the behaviour and property of composites has a lot of potential and for years has attracted researchers in different fields including physics, biology, engineering, mathematics, materials science, geophysics and hydrology.

1.2 The subject of this study

In this research, the purpose is to determine the effective property of multiphase composite materials that are made up of periodic structures [Moosavi and Sarkomaa, 2002a; Moosavi et al., 2002b; Moosavi and Sarkomaa, 2003a; Moosavi and Sarkomaa, 2003b; Moosavi and Sarkomaa, 2003c]. For the sake of greater familiarity, the formulations will be given mainly in the context of thermal conductivity, but the studied properties can be considered to be all those listed by Batchelor [1974] that are mathematically equivalent (recently Torquato [2002] has provided a similar table with more details). These properties include thermal and electrical conductivity, dielectric permittivity, magnetic permeability, mobility, the permeability of a porous medium, the modulus of torsion in a cylindrical geometry and the
effective mass in bubbly flow. The inclusions studied in this thesis are in the shape of circular cylinders or spheres; but also composites with periodic arrays of elliptical cylinders are examined. The basic formulations and results can be used for any purpose, although here the focus is applications in which the effect of one or more of the phases is neglected. For coated composites, the interesting behaviour reported for singly coated circular cylinders is considered. A further generalisation of this phenomenon is provided and extended to multicoated systems. For multiphase non-coated composites, cases in which the effects of phases with perfect and imperfect interfaces can be neglected, will be explained.

1.3 Motivation for selecting the cases for the study

1.3.1 Periodic composites with ideal inclusions

Only a few composites can be considered periodic and as having ideal inclusions. However, it should be noted that accurate calculation of the effective properties of real structures can be very difficult if not prohibitive. Ideal structures are under consideration here, since the mathematics involved in these systems is manageable and the effective property may be calculated to a high degree of accuracy. The results can be useful for understanding the interplay between microstructures and the effective property of real structures, and specifically those which can be approximated with the use of periodic structures. Also, the results provide a way of testing well-known classical numerical methods such as the boundary element method, finite difference method or finite element method [Baltz et al., 1997].

1.3.2 Coating composites

In many cases it is necessary to coat the inclusions; one such case is for the purpose of increasing the wettability and adhesion of the inclusions and the matrix. When the enhancing effect of the inclusions is not sufficient, a coating layer may modify the behaviour of the system. For protection from chemical reactions, a suitable coating layer can also be applied. In some cases, the coating layer is unwanted but occurs because of many problems in the production processes. For instance, due to a mismatch in thermal expansion, a coating layer with a third material may appear between the inclusions and the matrix. In some cases,
modelling a system as a coated one may provide reasonable results, even though the system is not exactly coated. This is the case for wet wood for which the moisture is considered to be a coating layer. Therefore, extending the formulations to coated systems may have many implications.

1.3.3 Composites with interfacial resistance

Most of the research has been performed assuming an ideal interface, but interfacial resistance may occur because of a variety of phenomena, such as physical irregularities at the boundaries, the presence of impurities, reaction on the surface of inclusions, acoustic mismatch at cryogenic temperature, or the presence of a gap between the inclusions and the matrix [Shai, 1982; Sanokawa, 1968; Eardley, 1973; Bhatt, 1992; Little, 1959; Torquato, 1995]. It is very important to take this effect into account, as the effective conductivity of the system may be significantly changed and a system with conducting inclusions may behave like a system that has non-conducting inclusions. In a more general case, the effect of interfacial resistance can be modelled assuming that there is a coating layer around the inclusions. However, in some cases, interfacial resistance can be characterised by introducing a non-dimensional parameter assuming that the interface has no thickness and that interfacial resistance is concentrated on the surface of the inclusions. This is the case, for example, with Kapitza resistance [Little, 1959; Torquato, 1995] or when the Knudsen number in the gap is considerable.

1.3.4 Multiphase composites

The behavior demonstrated by multi-phase systems can be completely different from that understood on the basis of two-phase systems. Also, extending the discussion to multi-phase cases introduces further generalisations into the formulations and relations.

1.4 Earlier studies

Contrary to general belief, the knowledge required for producing composite materials is not new. For example, archaeological studies show that the inhabitants of Finland were able to produce fibre-reinforced ceramics 4000 years ago [Lukkassen, 2002]. The scientific
investigation for deriving the effective property of composites is also old and begins from the work done by Maxwell [1873], Rayleigh [1892] and Einstein [1906].

In his treatise, Maxwell [1873] outlined the procedure for calculating the effective conductivity of composite materials that have a very small volume fraction of randomly arranged sphere-shaped inclusions, and derived a first-order relation of the volume fraction for the effective conductivity of these materials. A considerable improvement was made to Maxwell’s relation by Jeffrey [1973] who considered the interactions between the spheres using a methodology put forward by Batchelor [1972] and was successfully able to obtain a second-order relation. Chiew and Glandt [1983] later presented a modified version of Jeffrey’s formulation. Other research calculating the transport properties of composites with random arrangements can be found in reports by Sangani and Yao [1988], Bush and Soukoulis [1995], Kirchner et al. [1998] and others.

The research into periodic structures was initiated by Lord Rayleigh [1892]. Rayleigh took into account composites made up of periodic arrays of circular cylinder- and sphere-shaped inclusions. By describing the polarisation of each sphere in an external field using an infinite set of multipole moments, Rayleigh derived a relation for calculating the effective conductivity (electrical or thermal) of these materials of \( \mathcal{O}(f^{10/3}) \), where \( f \) is the volume fraction. Rayleigh’s methodology turned out to be problematic. Rayleigh decided to use an arbitrary method for calculating one parameter (lattice sum \( S_2 \)) included in his methodology, without explaining the reason; therefore, his method has been questioned by several researchers [Jeffrey, 1973]. McKenzie and McPhedran [1978] modified the Rayleigh method and explained the physics and mathematics in the problematic section of Rayleigh’s procedure (see also Poulton et al. [1999]). Rayleigh’s methodology has since been validated by many researchers. It is powerful and can be extended to electromagnetic [Nicorovici et al., 1994], elastostatic [McPhedran et al., 1994] and elastodynamic [Movchan et al., 1997] problems.

Runge [1925] studied the effective property of composites with periodic arrays of coated circular cylinders, but the core of the system considered by Runge had a property equal to that of a matrix. The discussion was generalised by Israelachvili et al. [1976] and Ninham and
Sammut [1976]. Mentuaful and Todreas [1994] derived a more developed explicit relation for the effective property of these composites. Nicorovici et al. [1993a] studied the case in more detail in the context of dielectric permittivity and reported strange behaviour for these composites. The same authors later extended the results to composites made up of randomly arranged coated circular cylinders and as well as to composites made up of periodic and random arrays of coated-spherical inclusions [Nicorovici et al., 1993b; Nicorovici et al., 1995]. Lu and Lin [1995; 1997] used the coating procedure for the purpose of modelling interfacial resistance in composite materials. Lu et al. [1996; 1997] have also presented the necessary changes needed to extend the Maxwell methodology to coated systems. For non-coated multi-phase composite materials, the work of McPhedran [1984] can be indicated who considered calculating the effective transport properties of three-phase composite materials having two different types of spherical inclusions arranged in the CsCl lattice (i.e., two intermeshed simple cubic lattices). More recently, Whites [2000] and Wu and Whites [2001] have developed a formulation for calculating efficiently numerically the effective property of multi-phase materials made up of periodic structures composed of spheres or cylinders, within the context of permittivity.

In addition to composites made up of inclusions in the shape of spheres or circular cylinders, composites made up of inclusions of other shapes have also been investigated, for example composites made up of inclusions in the shape of elliptical cylinders [Obdam et al., 1987; Nicorovici et al., 1996] or spheroids [Lu, 1998]. Schulgasser [1992] and Fel et al [2000] have provided some examples of structures whose the effective property can be easily found by using the Keller reciprocal relation [Keller, 1964]. A simple example could be a square checkerboard, which has been widely studied [Craster et al., 2001]. The case of a rectangular checkerboard, however, requires a considerable effort [Obnosov, 1999]. The effective conductivity of materials with square cylinders has been studied by Andrianov et al. [1999], who have applied the Padé approximation. More generally, Obnosov et al. [1999] have considered rectangular and triangular inclusions using complex variables.

Instead of considering a composite material and then calculating the effective property, it is possible to design composites with a specific property. Recently, Torquato et al. [2001] and Hyun et al. [2001, 2002] have adopted optimisation techniques for this purpose (the so-called
Target-Optimisation method). In this method, the unit cell is divided into many cells, each of which contains the material of the matrix or the other phases. Using numerical procedures, the cells are gradually moved until they yield a final structure that has the effective target property.
2. COMPOSITE MATERIALS WITH PERIODIC ARRAYS OF CIRCULAR CYLINDERS

In this chapter the problem of calculating the effective transport property of composite materials with circular cylindrical inclusions is discussed. First, the simplest case will be considered, i.e. one in which the cylinders are uniform and solid and the interface has no resistance, and the solution given by Rayleigh [1892] is explained. After that multiphase cases will be considered. Multiphase cases can occur as a result of the coating of the inclusions [Moosavi and Sarkomaa, 2002a] or the presence of different types of inclusions in the system [Moosavi and Sarkomaa, 2003a]. Both these cases will be taken into account separately and the behaviour of these systems explained. The effect of interfacial resistance will also be discussed [Moosavi and Sarkomaa, 2003b].

2.1 Two-phase composites with arrays of uniform and solid circular cylinders

Let us consider composite materials that are made up of uniform and solid inclusions of a circular cylindrical shape and arranged in a rectangular array with periodicities equal to a unity in the y-direction and b in the x-direction and immersed in a matrix with unit conductivity, as depicted in Fig. 2.1(a). The radius and the reduced conductivity of the inclusions will be titled by a and k, respectively. This way, the unit cell of the system would be a rectangular cylinder with sides equal to b and c, in the x- and y-directions, respectively, having a circular cylindrical inclusion with conductivity k and volume fraction \( f = \pi a^2 / b \) in the middle, as shown in Fig. 2.1(b).

The problem under study is deriving the effective conductivity of the system in the x- and y-directions. The effective conductivity can be simply obtained along the axis of the cylinders by using the arithmetic average technique, i.e., \( 1 - f + kf \).
Suppose that a uniform field of magnitude $E_{ext}$ is applied externally along the $x$-axis of the system in the negative direction. Thereby, the temperature inside the cylinder and the matrix in the polar coordinates $(r, \theta)$ where $\theta$ is measured from the $x$-axis can be expressed as:

$$T_1 = C_0 + \sum_{j=1}^{\infty} r^j (C_j \cos \theta + C'_j \sin \theta) \quad r \leq a$$

$$T_2 = A_0 + \sum_{j=1}^{\infty} \left[ (A_j r^j + B_j r^{-j}) \cos \theta + (A'_j r^{-j} + B'_j r^j) \sin \theta \right] \quad r > a$$

The periodicity of the system implies that $C_0$ and $A_0$ differ from one cell to another, but the other coefficients are essentially the same for all cells. Because of the symmetry of the temperature around $\theta = 0$, $C_j'$, $A_j'$ and $B_j'$ will be neglected. Also, the temperature is anti-symmetric around $\theta = \pi/2$, and therefore, $l$ can only be an odd number. As a result, the temperature functions can be reduced to the following:

$$T_1 = C_0 + \sum_{n=1}^{\infty} C_{2n-1} r^{2n-1} \cos(2n-1)\theta \quad r \leq a$$

$$T_2 = A_0 + \sum_{n=1}^{\infty} \left[ A_{2n-1} r^{2n-1} + B_{2n-1} r^{-2n+1} \right] \cos(2n-1)\theta \quad r > a$$
Next, the unknown coefficients will be derived. In the interface, the temperature and heat flux are continuous. Thus, we have

\[ T_1 = T_2, \quad k \frac{\partial T_1}{\partial r} = \frac{\partial T_2}{\partial r} \quad r = a \]  

(2.5)

Applying the above-mentioned boundary conditions, the coefficients of the temperature functions can be related to each other, i.e.,

\[ A_{2n-1} = \frac{B_{2n-1}}{\gamma_{2n-1} a^{4n-2}}, \quad C_{2n-1} = \frac{B_{2n-1}}{\chi_{2n-1} a^{4n-2}}, \]  

(2.6)

(2.7)

where

\[ \gamma_{2n-1} = \frac{1-k}{1+k}, \quad \chi_{2n-1} = \frac{1-k}{2} \]  

(2.8)

As can be seen, \( \gamma_{2n-1} \), which we can be referred to as multipolar polarisability, and \( \chi_{2n-1} \) are not \( n \)-dependent, but since they are, in general (for the case of coated cylinders or in the presence of resistance), functions of \( n \), they will be kept in this form.

The temperature functions cannot still be determined since the relations given in (2.6) and (2.7) are relations between the coefficients only and do not provide suitable equations in terms of the unknowns; a further series of relations between the coefficients is required. Many methods known nowadays, such as the Rayleigh method [1892], Zuzovski-Brenner method [1977], collocation scheme [Lu and Lin, 1994], inclusion model [Lu, 1998], and others have been considered for this purpose.

Here, the Rayleigh method is used, as it is the oldest and has received a lot of attention in the literature [Meredith and Tobias, 1960; Mcphedran and Mckenzie, 1978; Perrins et al., 1979; Cheng and Torquato, 1997]. It is based on the fact that the temperature around the origin, when origin not included, can be considered due to terms originating at infinity and at the other lattice sites. The reason is as follows: the temperature function given in Eq. (2.4)
consists of two types of terms. The terms that contain $r^{-2n+1}$ are clearly due to the sources situated at the origin, since by increasing the distance from the origin these terms diminish. The terms that contain $r^{2n-1}$ cannot be due to the sources at the origin because they increase when $r$ increases; therefore they originate from other existing sources in the system. The external field for any point placed in $(x, y)$ leads to a temperature increase equal to $E_{ext} x$. For this point, sources situated on the axis of the $j$th cylinder will also lead to a temperature increase equal to

$$\sum_{n=1}^{\infty} B_{2n-1} \cos(2n-1) \theta_j / r_{j}^{2n-1}$$

where $(r_j, \theta_j)$ is polar coordinate of the point when measured from the $j$th cylinder center. With this explanation the following relation can be written:

$$A_0 + \sum_{n=1}^{\infty} A_{2n-1} r^{2n-1} \cos(2n-1) \theta = E_{ext} x + \sum_{j=0}^{\infty} \sum_{n=1}^{\infty} B_{2n-1} / r_j^{2n-1} \cos(2n-1) \theta_j$$

(2.9)

The left-hand side of Eq. (2.9) can be considered as the real part of the relation

$$A_0 + \sum_{n=1}^{\infty} A_{2n-1} (x + iy)^{2n-1}$$

(2.10)

The right-hand side can also be written as the real part of the following:

$$E_{ext} (x + iy) + \sum_{j=0}^{\infty} \sum_{n=1}^{\infty} B_{2n-1} [x - \alpha_j + i(y - \eta_j)]^{-2n+1}$$

(2.11)

where $\alpha_j$ and $\eta_j$ are coordinates of the center of the $j$th cylinder measured from the origin. Now successive differentiation with respect to $x$ on both sides of the above is performed and the results at the origin evaluated (this can be done at any other point [McKenzie et al., 1978]). In this manner the following equations are obtained:
where \( S_n = \sum_{j \neq 0} (\alpha_j + i\eta_j)^{-n} \) are the lattice sums. For more details on calculating the lattice sums, the reader can refer to chapter 6. The above set of equations can be rewritten as

\[
A_2 + B_1 S_4 + \frac{3!}{2!} B_3 S_6 + \cdots = E_{ext} \\
3! A_2 + 3! B_1 S_6 + \frac{5!}{2!} B_3 S_8 + \cdots = 0 \\
5! A_2 + 5! B_1 S_8 + \frac{7!}{2!} B_3 S_{10} + \cdots = 0
\] (2.12)

where \( \delta_{nl} \) represents the Kronecker delta (1 for \( n=1 \), otherwise 0). Using relation (2.6), the following expression is finally obtained:

\[
A_{2n-1} + \sum_{m=1}^{\infty} \left( \frac{2n + 2m - 3}{2n-1} \right) S_{2n+2m-2} B_{2m-1} = E_{ext} \delta_{n1}, \quad (n = 1, \ldots, \infty)
\] (2.13)

All the unknown coefficients can be derived by solving the above set of equations and using (2.6) and (2.7). By examination of this linear system, it is found that this is a system of linear algebraic equations with infinite unknowns. The aim here is not to try to solve the system of equations totally, but to concentrate, instead, on deriving only a few values of \( B \). This is because considering \( B_{2n-1} \) for a sufficiently large \( n \) has no significant effect on the temperature values. The set of equations can be solved using different well-established methods such as lower-upper decomposition (LU) and singular value decomposition (SVD) methods. When the volume fraction or conductivity of the inclusions increases, more terms should be considered. To give the reader an estimation on the number of terms for consideration, some of the results of Perrins et al. [1979] for the square array \( (b=1) \) are reported in Table 2.1. As can be seen in this table the most difficult cases happen for perfectly conducting cylinders near to contact.
Table 2.1. The number of terms that should be considered to obtain an accuracy of 5 decimal digits (a maximum percent relative error of 0.01) for the effective conductivity of composites with periodic cylinders in a square array.

This makes it possible to obtain the temperature functions, but there is still have no relation for calculating the effective conductivity of the system. This can be done using different methods. Rayleigh [1892] used Green’s theorem which will be explained below for uniform solid cylinders. For the case of three-phase non-coated cylinders, however, a volume averaging method [Lu and Lin, 1995; Cheng and Torquato, 1997], which can be more confidently applied to a case involving an imperfect interface, will be explained.

### 2.1.1 Green’s theorem and the effective conductivity

Based on Green’s theorem for functions $\varphi$ and $\psi$ with continuous second derivatives, the following relation, which is Green’s second identity, can be written [Spiegel, 1968]:

$$
\int_V (\psi \nabla^2 \varphi - \varphi \nabla^2 \psi) \, dv = \oint_{\sigma} \left( \psi \frac{\partial \varphi}{\partial n} - \varphi \frac{\partial \psi}{\partial n} \right) \, d\sigma, 
$$

(2.15)

where $V$ and $\sigma$ are the total volume and surface area, respectively. If both $\psi$ and $\varphi$ satisfy the Laplace equation through the volume, the following can be written:

$$
\oint_{\sigma} \left( \psi \frac{\partial \varphi}{\partial n} - \varphi \frac{\partial \psi}{\partial n} \right) \, d\sigma = 0
$$

(2.16)

Now, let us suppose that $\psi = x$, $\varphi = T$ and that the medium being investigated is the unit cell of the composite material under study. As a result on can obtain
\[ \int_{\sigma_{ext}} \left( x \frac{\partial T}{\partial n} - T \frac{\partial x}{\partial n} \right) d\sigma = 0 \quad \sigma_{cell} = \sigma_l + \sigma_r + \sigma_b + \sigma_t + \sigma_c \quad (2.17) \]

Here, \( \sigma_l, \sigma_r, \sigma_b, \sigma_t \) refer to the left, right, bottom and top surface boundaries of the unit cell, respectively. \( \sigma_c \) is the surface of the cylinder inside the unit cell. The integral on surfaces \( \sigma_b \) and \( \sigma_t \) is zero because \( \partial x/\partial n = \partial T/\partial n = 0 \). Also, we have

\[ \int_{\sigma_r, \sigma_l} x \frac{\partial T}{\partial n} d\sigma = \int_{0}^{1} (x_r - x_l) \frac{\partial T}{\partial x} dy = b \int_{0}^{1} \frac{\partial T}{\partial x} dy = bG \quad (2.18) \]

\[ \int_{\sigma_r, \sigma_l} T \frac{\partial x}{\partial n} d\sigma = (T_r - T_l) = -bE_{ext} \quad (2.19) \]

\[ \int_{\sigma_r} \left( x \frac{\partial T}{\partial n} - T \frac{\partial x}{\partial n} \right) d\sigma = \int_{0}^{2\pi} \left( A_1 a^2 + B_1 \right) \cos^2 \theta \ d\theta - \int_{0}^{2\pi} \left( A_1 a^2 - B_1 \right) \cos^2 \theta \ d\theta = 2\pi B_1 \quad (2.20) \]

In (2.18), \( G \) is the average gradient. From the above

\[ bG - bE_{ext} + 2\pi B_1 = 0 \quad (2.21) \]

can be obtained and, as a result, the effective conductivity of the system is

\[ k_e = \frac{G}{E_{ext}} = 1 - \frac{2\pi B_1}{bE_{ext}} = 1 - \frac{2\beta l_A}{E_{ext}} \quad (2.22) \]

As can be seen, knowing \( B_1 \) is enough for obtaining the effective conductivity of the system. The relative conductivity of the medium without inclusions is clearly equal to a unity; thereby, the term \( 2\pi B_1 / (bE_{ext}) \) is produced as a result of the presence of inclusions in the matrix. This term can be positive (an impairing case), negative (an enhancing case) or equal to zero.
2.1.2 The effective conductivity for the perpendicular direction and Keller theorem

In general, the effective conductivity is a tensor of rank two (see Torquato [2002] for details). For the case \( b \neq 1 \), the effective conductivity in the \( y \)-direction is not equal to that in the \( x \)-direction and should be calculated. For this purpose, the same method as explained for the parallel direction may be applied. If the system is rotated by an angle of \( \alpha = \pi/2 \), we get

\[
\frac{B'_{2n-1}}{\gamma_{2n-1} a^{4n-2}} + \sum_{m=1}^{\infty} \left( \frac{2n + 2m - 3}{2n - 1} \right) S'_{2n+2m-2} B'_{2m-1} = E_{\text{ext}} \delta_{n1},
\]  

(2.23)

where \( S'_{j} \) are the lattice sums over the cylinders in this new position. It can be proven that \( S'_{2n} = (-1)^n S_{2n} \) for \( n > 1 \) and also that \( S'_2 = 2\pi/b - S_2 \) [Nicorovic and McPhedran, 1996]. The effective conductivity now is

\[
k'_e = 1 - \frac{2\pi B'_1}{b E_{\text{ext}}} = 1 - \frac{2f Y_1 A'_1}{E_{\text{ext}}}
\]  

(2.24)

The effective conductivities in the parallel and perpendicular directions have been linked to each other through the well-known Keller reciprocal relation [Keller, 1964; Milton, 1988; Fel et al., 2000], i.e.,

\[
k_e(k,1) \times k'_e(1/k,1) = 1
\]  

(2.25)

This fact can be easily proven. By considering that reversing the conductivity of the phases only makes the sign of \( \gamma \) negative and applying the above-mentioned property of the lattice sums (see also Perrins et al., [1979]) from relation (2.23), it is found that

\[
\frac{(-1)^n B'_2}{\gamma_{2n} a^{4n-2}} + \sum_{m=1}^{n} \left( \frac{2n + 2m - 3}{2n - 1} \right) S'_{2n+2m-2} (-1)^m B'_{2m-1} = E_{\text{ext}} \left( 1 - \frac{2\pi B'_1}{b E_{\text{ext}}} \right) \delta_{n1}
\]  

(2.26)

By using Eq. (2.24) and comparing the above relation with (2.14), it is found
\[
\frac{B'_{2n-1}}{k'_e(1/k_1,1)} = (-1)^n B_{2n-1}
\] (2.27)

Writing the above relation for \( n = 1 \) and using Eq. (2.24) again gives

\[
k'_e(1/k_1,1) = 1 + \frac{2\pi k'_e(1/k_1,1)B_1}{bE_{ext}}
\] (2.28)

By applying Eq. (2.22), the following relation is finally obtained

\[
k_e(k_1,1) \times k'_e(1/k_1,1) = 1
\] (2.29)

### 2.1.3 Explicit forms for the effective conductivity

As can be seen in Table (2.1), for low volume fractions or when the conductivity of the cylinders is small, considering a few values of \( B_{2n-1} \) may yield reasonable results. It is more useful to derive an explicit relation for the effective conductivity of the system within these boundaries. On the basis of the method used for truncating (for example square or triangular manner) and the number of the unknowns taken into account, different expressions may be obtained [Manteufel and Todreas, 1994]. Using triangular truncation of the second order gives

\[
\frac{B_1}{\gamma_1 a^3} + S_2 B_1 + 3S_4 B_3 = E_{ext}
\] (2.30)

\[
\frac{B_1}{\gamma_3 a^6} + S_4 B_1 = 0,
\] (2.31)

whence

\[
k_e = 1 - \frac{2f}{1 + c_1 f - c_2 \gamma_1 f^4},
\] (2.32)

where \( c_1 = b S_2 / \pi \) and \( c_2 = 3S_4 (b/\pi)^4 \). In Table 2.2 the constants for some of the values of \( b \)
have been reported by calculating highly accurate values for the lattice sums [Movchan, 1997; Huang, 1999; Huang, 2001].

### 2.2 Multiphase composites with arrays of uniform and coated circular cylinders

The theory for coated cylinders (see Moosavi and Sarkomaa [2002a]) can be formulated in the same manner as that discussed in the case of solid cylinders. To start with, the solid cylinders given in Fig. 2.1 are replaced by the multi-coated ones shown in Fig. 2.2. As can be seen in Fig. 2.2, the multi-coated cylinders under study are made up of a core of radius $a_i$ and $N$-2 coating layers placed in the regions $a_{i-1} \leq r \leq a_i \ (i = 2, \ldots, N-1)$, respectively. With these considerations, the volume fractions occupied by the core and coating layers can be obtained from $f_i = \pi (a_i^2 - a_{i-1}^2)/b$, where $a_0 = 0$ and the total volume fraction can be expressed as $F = \sum_{i=1}^{N-1} f_i$. The conductivity of phase $i$ is denoted by $k_i$. For the composite, the temperature profiles inside the core, coating layers and the matrix can be expressed as:

$$T_1 = C_0 + \sum_{n=1}^{\infty} C_{2n-1} r^{2n-1} \cos(2n-1) \theta$$

$$T_i = A_0^i + \sum_{n=1}^{\infty} \left[ A_{2n-1}^i r^{2n-1} + B_{2n-1}^i r^{-2n+1} \right] \cos(2n-1) \theta \quad (i = 2, \ldots, N)$$
Following the same discussion as that given for solid cylinders, the following equation can be derived for the system:

\[
A_0^N + \sum_{n=1}^{\infty} A_{2n-1}^N r^{2n-1} \cos(2n-1)\theta = E_{ext} r \cos \theta + \sum_{j \neq 0} \sum_{n=1}^{\infty} B_{2n-1}^N r^{2n-1} \cos(2n-1)\theta_j
\]  

(2.35)

After performing the required steps explained in section 2.1, the governing equations of the system can be derived as

\[
\frac{B_{2n-1}^N}{\gamma_{2n-1}^N a_{N-1}^{4n-2}} + \sum_{m=1}^{\infty} \left( 2n + 2m - 3 \right) \delta_{2n+2m-2} B_{2m-1}^N = E_{ext} \delta_{n1},
\]  

(2.36)

where \( \gamma_{2n-1}^N \) can be obtained by successively applying the following procedure

\[
\gamma_{2n-1}^i = \frac{(k_i + k_{i-1}) a_{i-2}^{4n-2} + (k_i - k_{i-1}) \gamma_{2n-1}^{i-1} a_{i-1}^{4n-2}}{(k_i - k_{i-1}) a_{i-2}^{4n-2} + (k_i + k_{i-1}) \gamma_{2n-1}^{i-1} a_{i-1}^{4n-2}} \quad i > 2
\]  

(2.37)
which is the result of implementing the boundary conditions between the phases, i.e.

\[ T_i = T_{i+1} \quad \text{and} \quad k_i \frac{\partial T_i}{\partial r} = k_{i+1} \frac{\partial T_{i+1}}{\partial r} \quad r = a_i \quad (i = 1, \ldots, N - 1) \]  

(2.38)

The effective conductivity of the system can be derived again using Green’s theorem. In applying Green’s theorem, only the surface of the boundaries of the unit cell and that of the outermost coated cylinder, which is in contact with the matrix, are considered. Therefore, it is not surprising that the same formula is derived as that for solid cylinders, i.e.,

\[ k_e = 1 - \frac{2\pi B_1^N}{bE_{ext}} = 1 - \frac{2F \gamma_i^N A_i^N}{E_{ext}} \]  

(2.39)

### 2.2.1 Phase abandonment in multicoated composites

The behaviour of singly coated cylinders has been studied by Nicorovici et al. [1993a; 1993b; 1995]. The coating sequence effect has also been investigated by Lu [1997a]. Here the attention is mainly focused on the results reported by Nicorovici et al. The property selected by these authors was the dielectric constant, and therefore they were able to choose the property of the layers from \(-\infty\) to \(+\infty\). The dielectric constant expresses the ability of a dielectric to store electrostatic energy under the influence of an electric field. In electrostatic the equation \( \nabla.(\varepsilon \nabla H) = 0 \) needs to be solved, where \( \varepsilon \) is the dielectric constant and \( H \) the electric potential. There is also \( D = -\varepsilon \nabla H \) where \( D \) denotes electric flux density. These equations are mathematically equivalent to \( \nabla.(k \nabla T) = 0 \) and \( F = -k \nabla T \), respectively, in heat conduction. For some transport properties, such as dielectric constant, negative values are of physical significance and are realisable. Materials can be designed to exhibit negative values of certain transport properties, such as magnetic permeability (a constant of proportionality that exists between magnetic induction and magnetic field intensity), even though they do not normally exhibit negative values for these properties [Vessalago, 1968]. It is also possible to go further and design materials with two negative transport properties [Smith et al., 2000]. These materials may exhibit strange behaviour. For example, materials where both the
dielectric permittivity and magnetic permeability are negative (so-called left-handed materials) demonstrate a negative refractive index [Pendry et al., 2001].

Next, the discussion is extended to a multicoated case (see Moosavi and Sarkomaa [2002a]). The transport property is here denoted by \( \varepsilon \). As can be seen in Eq. (2.36), the term \( \xi_{2n-1}^N = 1/\left(\gamma_{2n-1}^N a_{N-1}^{4n-2}\right) \) plays an important role in the response of the system to the applied field, as this is the only part of the set of equations which contains information on the property and volume fraction of the layers. Therefore, if a completely different set of coating cylinders with \( N^* \) phases satisfies the condition \( \xi_{2n-1}^{N^*} = \xi_{2n-1}^N \), it can be applied instead of the original coated cylinders, and the effective transport property of the system in both states will be the same. For example, for the case of coating layer \( i \), for which \( \varepsilon_i = 0 \), \( \gamma_i^{+1} = 1 \) is derived. As can be seen, \( \gamma_i^{+1} \) does not contain any information on the property and radius of the layers under layer \( i \); therefore, they can be arbitrarily chosen. The same occurs when \( \varepsilon_i = \pm \infty \), which yields \( \gamma_i^{+1} = -1 \).

Now, a more interesting case is considered in which \( \varepsilon_1 + \varepsilon_{i-1} = 0 \). Nicorovici et al. [1993a] showed that for a singly coated system, cases \( \varepsilon_2 = -\varepsilon_1 \) and \( \varepsilon_2 = \varepsilon_1 \) surprisingly demonstrate the same response to the applied field. In other words, coated cylinders can be replaced by solid ones that have a property equal to that of the core and a radius equal to that of the coating layer. The reason is clear. Let us derive \( \xi_{2n-1}^3 \):

\[
\xi_{2n-1}^3 = \frac{\left(\varepsilon_3 - \varepsilon_2\right)\left(\varepsilon_2 - \varepsilon_1\right)a_1^{4n-2} + \left(\varepsilon_3 + \varepsilon_2\right)\left(\varepsilon_2 + \varepsilon_1\right)a_2^{4n-2}}{\left(\varepsilon_3 + \varepsilon_2\right)\left(\varepsilon_2 - \varepsilon_1\right)a_1^{4n-2} + \left(\varepsilon_3 - \varepsilon_2\right)\left(\varepsilon_2 + \varepsilon_1\right)a_2^{4n-2}} \times \frac{1}{a_2^{4n-2}}
\]

(2.40)

When \( \varepsilon_2 = \varepsilon_1 \) or \( \varepsilon_2 = -\varepsilon_1 \), \( \xi_{2n-1}^3 \) reduces to \( \left(\varepsilon_3 + \varepsilon_1\right)/\left(\varepsilon_3 - \varepsilon_1\right)a_1^{4n-2} \). Since all the parameters remain unchanged, the responses of the systems are exactly the same. It can also be shown that the cases \( \varepsilon_2 = -\varepsilon_3 \) and \( \varepsilon_2 = \varepsilon_1 \) conditionally produce the same response. The condition is that for the two-phase case, the radius of the dispersed phase must be equal to \( a_2^2/a_1 \), where \( a_1 \) and \( a_2 \) are the radii of the core and shell, respectively, for the three-phase system. This
result is important, since this way when \( a_1 \) and \( a_2 \) are both small but the ratio of \( a_2 / a_1 \) is large, the three-phase system will give the response of a two-phase system with the radius of the inclusions equal to \( a_2^2 / a_1 \), which can be completely considerable. As a result, the response of a concentrated system can be produced with a system that has a very small total volume fraction.

In the following, a multicoated system when the sum of the dielectric constant of two dispersed layers, \( i-1 \) and \( i \), is equal to zero, is considered. For this case

\[
\xi^i_{2n-1} = \frac{\varepsilon_{i+1} - \varepsilon_i + (\varepsilon_{i+1} + \varepsilon_i) \xi^{i}_{2n-1} a^{4n-2}_i}{\varepsilon_{i+1} + \varepsilon_i + (\varepsilon_{i+1} - \varepsilon_i) \xi^{i}_{2n-1} a^{4n-2}_i} \times \frac{1}{a^{4n-2}_i} \quad i \geq 1
\]

(2.41)

This relation would yield the same \( \xi^i_{2n-1} \) and, as a result, the same \( \xi^N_{2n-1} \) if layer \( i \) had the same property as layer \( i-1 \) and all the layers under layer \( i-1 \) were magnified by a factor of \((a_i/a_{i-1})^4\). Layer \( i-1 \) undergoes two changes: magnification by occupying the place of layer \( i \) and reduction due to the extension of layer \( i-2 \). Thus, this case can be materialised only if \( a_{i-1} > \sqrt{a_i a_{i-2}} \). This means that for the case where the property of the layers is equal to \((\varepsilon_1, \pm \varepsilon_1, \cdots, \pm \varepsilon_1, \varepsilon_2)\), the following can always be written:

\[
\varepsilon_{e}(\varepsilon_1, \varepsilon_1, \cdots, \varepsilon_1, \varepsilon_2) \times \frac{1}{\varepsilon_{e}(\varepsilon_1, \pm \varepsilon_1, \cdots, \pm \varepsilon_1, \varepsilon_2)} = 1
\]

(2.42)

The system satisfies the Keller reciprocal relation (see chapter 4); and thus we have

\[
\varepsilon_{e}(\varepsilon_1, \cdots, \varepsilon_N) \times \varepsilon'_{e}(1/\varepsilon_1, \cdots, 1/\varepsilon_N) = 1
\]

(2.43)

By applying (2.42) and (2.43), we obtain

\[
\varepsilon_{e}(\varepsilon_1, \varepsilon_1, \cdots, \varepsilon_1, \varepsilon_2) \times \varepsilon'_{e}(1/\varepsilon_1, \pm 1/\varepsilon_1, \cdots, \pm 1/\varepsilon_1, 1/\varepsilon_2) = 1
\]

(2.44)

In addition to inspecting \( \xi^i_{2n-1} \), let us now also study \( \xi^i_{2n-1} \) when \( \varepsilon_i + \varepsilon_{i-1} = 0 \), i.e.,
\[ \xi_{2n-1}^i = \frac{(\varepsilon_i - \varepsilon_{i-1}) + (\varepsilon_i + \varepsilon_{i-1})}{(\varepsilon_i + \varepsilon_{i-1}) + (\varepsilon_i - \varepsilon_{i-1})} \xi_{2n-1}^{i-1} a_{i-1}^{4n-2} \times \frac{1}{a_{i-1}^{4n-2}} \quad i \geq 1 \]  

(2.45)

An inspection of the above relation shows that when \( \varepsilon_i = -\varepsilon_{i-1} \), another equivalent system can be obtained differently. In this system, the layers \( 1, \ldots, i-3 \) have been extended by a factor of \( (a_{i-3}/a_{i-2})^i \). The layer \( i-1 \) now has the property equal to that of layer \( i-2 \) and its outer radius is \( a_{i-1} \times (a_{i-3}/a_{i-2}) \). This system can be materialized if \( a_{i-1} < \sqrt[4n-2]{a_{i-2}} \).

The results of the present study have been verified using the finite element method. Consider, for instance, the following simple example. Based on the above formulations for a triply coated system, cases \( \varepsilon_1 = -\varepsilon_2 = \varepsilon_3 \) and \( \varepsilon_1 = \varepsilon_2 = \varepsilon_3 \) should give the same response to the applied field. The results for both systems are given in Figures 2.3(a, b). As can be seen in both systems, the fields through the matrix are exactly equal, which means that both systems have exactly the same effective property.

![Figure 2.3](image)

**Figure 2.3** The equipotential contours inside a unit cell. The original system (a) and the equivalent system (b).
2.3 Three-phase composites with arrays of solid circular cylinders

In this section, the problem of calculating the effective conductivity of composites made up of two types of cylindrical inclusion arranged in a periodic array and embedded in a continuous phase is discussed [see Moosavi and Sarkomaa, 2003b], as depicted in Fig. 2.4. The configuration of the geometry selected for the study makes it possible to construct many periodic structures that can be extensively found in literature. First, the Rayleigh method will be developed for a three-phase composite system. Then, the algorithm is verified, comparing the results with some existing numerical results. Finally, the behaviour of the system is inspected. Only the mathematical algorithms for the \( x \)-direction will be explained. As outlined in section (2.1.2), the same mathematical formulation can be extended for the \( y \)-direction. Furthermore, the effective conductivities can be related to each other using the Keller theorem.

![Figure 2.4 The structure of the three-phase materials under study](image)

2.3.1 Governing equations

Suppose that the origin of cartesian coordinates has been placed at the centre of a cylinder of type one in a unit cell of the system in which the \( x \)- and \( y \)-axes are parallel to the sides of the unit cell (see Fig. 2.4). Furthermore, assume that the matrix of the composite under study has unit conductivity, and the periodicity of the system in the \( y \)-direction is equal to a unity for...
greater generality. Also the periodicity of the system in the $x$-direction is denoted by $b$. Applying these conditions, the conductivity of the cylinders is denoted by $k_1$ and $k_2$, the radiiuses by $a_1$ and $a_2$ and the volume fractions by $f_1$ and $f_2$ for the cylinders of type one and two, respectively. Let us assume that a uniform field of magnitude $E_{ext}$ has been applied along the $x$-axis of the system in the negative direction. By taking the center of one of the cylinders of type $i$ ($i = 1, 2$) as the origin of polar coordinates ($r, \theta$), the temperature within the cylinder can be given as

$$T_i(r, \theta) = C_0^i + \sum_{n=1}^{\infty} C_{2n-1}^i r^{2n-1} \cos (2n-1)\theta$$

(2.46)

and for the temperature outside the cylinder the following may be written

$$T_{m,i}(r, \theta) = A_0^i + \sum_{n=1}^{\infty} \left( A_{2n-1,i} r^{2n-1} + B_{2n-1,i} r^{-2n+1} \right) \cos (2n-1)\theta$$

(2.47)

where $m$ stands for the matrix. Note that as in the previous cases in (2.48) and (2.49), the terms of even degree are not present because of the anti-symmetry of the temperature profiles around $\theta = \pi/2$. At the surface of each type of cylinder, we have

$$T_i = T_{3i}, \quad k_i \frac{\partial T_i}{\partial r} = \frac{\partial T_{3i}}{\partial r}, \quad r = a_i$$

(2.48)

By applying the above boundary conditions, the following relations can be obtained:

$$A_{2n-1}^i = \frac{B_{2n-1}^i}{\gamma_{2n-1} a_i^{4n-2}}$$

(2.49)

$$C_{2n-1}^i = \frac{B_{2n-1}^i}{\chi_{2n-1} a_i^{4n-2}}$$

(2.50)

where
\[ \gamma_{2n+1}^i = \frac{1 - k_i}{1 + k_i}, \quad \chi_{2n-1}^i = \frac{1 - k_i}{2} \]  

(2.51)

In the same manner as explained for the two-phase case, the terms in (2.47) can be analyzed. By separating the effect of sources situated on the axes of the cylinders of type one and two the following can be written:

\[ A_0^i + \sum_{n=1}^{\infty} A_{2n-1}^i r^{2n-1} \cos((2n-1)\theta) = E_{\text{ext}}x + \]

\[ \sum_{j \neq 0} \sum_{m=1}^{\infty} \frac{B_{2m-1}^j}{r_{j,2m-1}} \cos((2m-1)\theta) + \sum_{j \neq 0} \sum_{m=1}^{\infty} \frac{B_{2m-1}^{2-\delta_{2j}}}{r_{j,2m-1}^{2-\delta_{2j}}} \cos((2m-1)\theta), \]  

(2.52)

where \( r_{j,2m-1} \) and \( \theta_{j,2m-1} \) are measured from the center of the \( j \)th cylinder situated in the array of cylinders of type \( i \). If the above equation is written in complex form [Moosavi and Sarkomaa, 2003a] and successive differentiation is performed with respect to \( x \) on both sides of the above equation, and the results evaluated at the origin of cylinder of type \( i \), the final result after using (2.49) would appear as

\[ \frac{B_{2m-1}^i}{\gamma_{2n+1}^{i+2m-2} + \sum_{m=1}^{\infty} \left( \frac{2n + 2m - 3}{2n - 1} \right) \left( S_{2n+2m-2}^i B_{2m-1}^i + S_{2n+2m-2}^{2-\delta_{2j}} B_{2m-1}^{2-\delta_{2j}} \right) = E_{\text{ext}}\delta_n, \]  

(2.53)

Here, \( S_n^i = \sum_{j \neq 0} (\alpha_{j,2m-1} + i\eta_{j,2m-1})^n \) are the lattice sums over the cylinders of type \( i \), where \( \alpha_{j,2m-1} \) and \( \eta_{j,2m-1} \) are the coordinates of center of the cylinder \( j \) of type \( i \) in the current polar coordinates.

### 2.3.2 Volume averaging technique for determining the effective conductivity of the system

Based on Fourier’s law, the effective conductivity of the system can be derived using the following formula:
\[
\langle F \rangle = -k_i \langle \nabla T \rangle
\]  

(2.54)

where \(\langle F \rangle = (1/V_{\text{cell}}) \int_{V_{\text{cell}}} F dV\) and \(\langle \nabla T \rangle = (1/V_{\text{cell}}) \int_{V_{\text{cell}}} \nabla T dV\) are the average heat flux and temperature gradient over the unit cell, respectively. The average heat flux can be considered because of the matrix and cylinders of type one and two, i.e.,

\[
\langle F \rangle = \frac{1}{V_{\text{cell}}} \left[ \int_{V_1} F dV + \int_{V_2} F dV + \int_{V_3} F dV \right]
\]  

(2.55)

or

\[
\langle F \rangle = -\frac{1}{V_{\text{cell}}} \left[ (k_1 - 1) \int_{V_1} \nabla T_1 dV + (k_2 - 1) \int_{V_2} \nabla T_2 dV + \int_{V_{\text{cell}}} \nabla T dV \right],
\]  

(2.56)

where \(V_1, V_2\) and \(V_3\) are the volumes of cylinders of type one and two and the matrix placed in the unit cell, respectively. The average temperature gradient can also be written as follows:

\[
\langle \nabla T \rangle = \frac{1}{V_{\text{cell}}} \left[ \int_{V_{\text{cell}}} \nabla T dV \right]
\]  

(2.57)

From Eqs. (2.56) and (2.57), we can obtain

\[
\langle F \rangle = \langle S_P \rangle_1 + \langle S_P \rangle_2 - \langle \nabla T \rangle,
\]  

(2.58)

where

\[
\langle S_P \rangle_i = \frac{1-k_i}{V_{\text{cell}}} \int_{V_i} \nabla T dV
\]  

(2.59)

or equivalently, using Green’s first identity [Spiegel, 1968], we have

\[
\langle S_P \rangle_i = \frac{1-k_i}{V_{\text{cell}}} \int_{\sigma_i} T n dS
\]  

(2.60)
Here, $\sigma_i$ is the surface of inclusion of type $i$ and $n$ expresses the unit outward normal vector to the surface. After using the orthogonality properties of trigonometric functions, the following can be obtained:

$$\langle S_p \rangle_i = \frac{1-k_i}{V_{cell}} \int_0^{2\pi} a_i^2 C_i^i \cos^2 \theta \ d\theta = \frac{\pi a_i^2 (1-k_i)}{V_{cell}} C_i^i \ i = \frac{2\pi B_i^i}{V_{cell}}$$  \hspace{1cm} (2.61)

By substituting the resultants in Eq. (2.58) and taking into account $\nabla T = E_{ext} i$ and $V_{cell} = b$, the final result for the effective conductivity can be given as

$$k_e = 1 - \frac{2\pi (B_1^i + B_2^2)}{bE_{ext}} = 1 - \frac{2f_1'\gamma_1^i A_1^i + 2f_2\gamma_2^2 A_2^2}{E_{ext}}$$  \hspace{1cm} (2.62)

or more generally, for a case in which $M$ cylinders are placed in the unit cell, the effective conductivity of the system can be obtained using

$$k_e = 1 - 2\pi \sum_{i=1}^{M} \frac{B_i^i}{(V_{cell} E_{ext})}$$  \hspace{1cm} (2.63)

### 2.3.3 The effective conductivity in explicit forms

To assist calculating the conductivity of the system under study, some relations are here derived in explicit forms. Based upon the triangular truncation of second order, the following can be obtained:

$$k_e = 1 - \frac{2f_1}{(\lambda_1 \lambda_2 - \xi_1 \xi_2) / (\lambda_2 - \xi_2)} - \frac{2f_2}{(\lambda_1 \lambda_2 - \xi_1 \xi_2) / (\lambda_2 - \xi_2)}$$  \hspace{1cm} (2.64)

with

$$\lambda_i = \frac{1}{\gamma_i^i} + c_1 f_{i} - c_2 \gamma_i^i f_{i}^4 - c_3 \gamma_i^{2-\delta_2} f_{i} f_{i}^{3-\delta_2}$$  \hspace{1cm} (2.65)
\[ \xi_i = c_i f_i - c_5 \left( \gamma_{i,1}^2 f_i^2 + \gamma_{i,2}^2 f_i f_i f_i f_i \right), \tag{2.66} \]

where \( c_1 = S_{2,1}^2 b / \pi \), \( c_2 = 3(b / \pi)^4 S_{2,1}^4 \), \( c_3 = 3(b / \pi)^4 S_{2,1}^2 \), \( c_4 = S_{2,1}^2 b / \pi \) and \( c_5 = 3S_{2,1} S_{2,2}^2 (b / \pi)^4 \).

The higher orders may be ignored to obtain a simpler relation

\[ k_f = 1 - \frac{2f_1}{\omega / u_1} - \frac{2f_2}{\omega / u_1}, \tag{2.67} \]

where

\[ \omega = \left( 1 / \gamma_i^1 + c_1 f_i \right) \left( 1 / \gamma_i^2 + c_1 f_i \right) - c_4 f_i f_i, \tag{2.68} \]

\[ \nu_i = 1 / \gamma_i^1 + (c_1 - c_4) f_i \tag{2.69} \]

The constants for cases \( b = 1 \) and \( b = \sqrt{3} \) (the parallel and perpendicular directions) are listed in Table 2.3.

### 2.3.4 Behaviour of the system and phase abandonment

Before starting the discussion on the results of the three-phase system, it is helpful to verify the validity of the extension to the three-phase system. A series of calculations for two-phase composites with uniform cylinders arranged either in square \((b = 1)\) or hexagonal
orders \( b = \sqrt{3} \) will be performed and the results then compared with those reported by Perrins et al. [1979].

![Figure 2.3](image-url) A comparison between the present results and those reported by Perrins et al. [1979].

The two-phase cases can be constructed from the three-phase one simply by applying \( f_1 = f_2 \) and \( k_1 = k_2 \). For this purpose highly accurate values for lattice sums over cylinders of type one and two were derived and Eq. (2.53) \( i=1,2 \) was solved numerically using LU decomposition method [Press et al., 1986]. Taking into account 100 unknowns of \( B_{2n-1,1} \) and \( B_{2n-1,2} \) gives us a measure of obtaining accurate results for all the volume fractions and conductivities considered [Perrins et al., 1979]. In Fig. 2.3 the results are compared for both the square and hexagonal arrays for the most challenging case, i.e., the case of perfectly conducting cylinders. As can be seen for all the values of volume fractions, the results of the two studies are in excellent agreement.

Figure 2.4 shows a typical result for the effective conductivity of the system for both the parallel and perpendicular directions. The volume fractions are \( f_1 = 0.4 \) and \( f_2 = 0.4 \), and the periodicity in the \( x \)-direction was supposed to be \( b = \sqrt{3} \).
Figure 2.4 The contours of the effective conductivity for the perfect interface case. $f_1 = 0.4$ and $f_2 = 0.4$

For deriving the conductivity of the system in the perpendicular direction either Eq. (2.53) can be solved and Eq. (2.62) applied or, alternatively, the Keller theorem can be used for this purpose. Through a careful examination of this figure, it appears that increasing or decreasing the conductivity of both types of cylinders may enhance or diminish the conductivity of the system, respectively, which is obvious and remains correct for both directions. Furthermore, the system demonstrates higher effective conductivity in the perpendicular direction. This behavior is a consequence of the rectangular shape of the unit cell which provides a more (less) important role for the cylinders with lower conductivity in the parallel (perpendicular) direction. Interestingly, for the case of mono-sized cylinders with $k_1 = \infty$ and $k_2 = 0$, increasing the volume fraction of the cylinders causes the conductivity of the system to approach zero in the parallel direction and approach infinity in the perpendicular direction (see Table 2.4). When perfectly insulating cylinders touch each other, they form a barrier which prevents heat flow in the parallel direction. This behavior can also be observed for all systems for which $b > 1$. For the case $b = 1$, however, the system is isotropic and the same results can be expected for both directions. For this case, the same type cylinders are not able to touch each other and a limited value for the effective conductivity of the system can be
expected. Surprisingly, it was found that the effective conductivity of the system is simply a unity.

Table 2.4 The effective conductivity of three-phase materials made up of mono-sized cylinders for which $k_1 = 0$ and $k_2 = \infty$.

</tr>
</tbody>
</table>

This result can be confirmed using the Keller theorem as follows: since the system is isotropic and interchange between the material of the cylinders keeps the system unchanged, using Eq. (2.43) it is possible to get

$$k_e (k,1/k,1) \times k'_e (1/k,k,1) = k_e (k,1/k,1) \times k_e (k,1/k,1) = 1$$

Considering $k = 0$ proves our case. Sculgasser [1992] has shown that in a three-phase system with interchangeable phases (see Fig. 2.5), when one of the phases has conductivity equal to $k$ and the two remaining phases are perfectly conducting and non-conducting, the effective conductivity of the system is $k$. From the above results, it is clear that it is not necessary for the first phase to be interchangeable, and it can simply be a matrix.

For the case $b = 1$ with non-equal sized cylinders, if $f_i \leq \frac{\pi}{4} (\sqrt{2} - 1)^2$, $f_{2,\delta_2}$ can be increased freely to the touching value limit, and the effective conductivity of the system can approach infinity or zero, depending on the conductivity of the touching cylinders.
Figure 2.5 The structure investigated by Schulgasser et al. [1992]

Figure 2.6 shows the results of the effective conductivity for a system with a lower total volume fraction, i.e., $f_1 = 0.4$ and $f_2 = 0.2$. $b$ as before is equal to $\sqrt{3}$. A comparison with Fig. 2.4 reveals that the case $k_1 = k_2 = 1$ is the only situation in which both systems for the given conductivities present the same effective conductivity. In this situation $\gamma_1 = \gamma_2 = 0$, which leads to $B_1^1 = B_1^2 = 0$, and as a result, $k_e = 1$.

Figure 2.6 The contours of the effective conductivity for the perfect interface case. $f_1 = 0.4$ and $f_2 = 0.2$. 
Figures 2.4 and 2.6 also show that having cylinders with conductivities equal to the conductivity of the matrix is not the only condition for the effective conductivity to be equal to the conductivity of the matrix. In fact, this case is a special state of the following general situation:

\[ B_1^1 + B_1^2 = f_1 \gamma_1 A_1^1 + f_2 \gamma_2 A_1^2 = 0 \]  

(2.71)

The importance of the situation \( k_1 = k_2 = 1 \) (\( B_1^1 = B_1^2 = 0 \)) is that it is independent of the values of \( f_1, f_2 \) and \( b \), and for all these situations, it would be found that \( k_e = 1 \), which is physically obvious. This behavior does not hold for the other values of the conductivities.

### 2.3.5 Heat transfer with interfacial resistance

If the dimensionless interfacial resistances [Torquato and Rintoul, 1995] are denoted by \( R_i \) \((i = 1, 2)\), the boundary conditions given in (2.48) will change to the following shape [Moosavi and Sarkomaa, 2003b]:

\[
\frac{k_i}{R_i a_i} (T_i - T_{3i}) = -k_i \frac{\partial T_i}{\partial r} = -\frac{\partial T_{3i}}{\partial r} \text{ on } a_i \ (i = 1, 2)
\]

(2.72)

Therefore, for the coefficients of the temperature profiles, we obtain

\[
A_{2n-1}^i = \frac{B_{2n-1}^i}{\gamma_{2n-1}^i a_{4n-2}^i}
\]

(2.73)

\[
C_{2n-1}^i = \frac{B_{2n-1}^i}{\chi_{2n-1}^i a_{4n-2}^i},
\]

(2.74)

where

\[
\gamma_{2n-1}^i = \frac{1 - k_i + R_i (2n - 1)}{1 + k_i + R_i (2n - 1)} \quad \chi_{2n-1}^i = \frac{1 - k_i + R_i (2n - 1)}{2}
\]

(2.75)
When the interface is imperfect, the volume averaged heat flux may be formulated using the same formula as for a perfect case, but the volume-averaged temperature will contain extra terms because of the temperature jump in the interfaces, i.e.,

\[
\langle \nabla T \rangle = \frac{1}{V_{cell}} \left[ \int_{V_{cell}} \nabla T \, dV + \int_{\sigma_1} (T_{31} - T_1) n \, dS + \int_{\sigma_2} (T_{32} - T_2) n \, dS \right],
\]  

(2.76)

Therefore, the volumes averaged of the temperature and flux can be related to each other by

\[
\langle F \rangle = \langle S_p \rangle_1 + \langle S_p \rangle_2 + \langle S_i \rangle_1 + \langle S_i \rangle_2 - \langle \nabla T \rangle,
\]  

(2.77)

where

\[
\langle S_p \rangle_i = \frac{1 - k_i}{V_{cell}} \int_{V_i} \nabla T_i \, dV
\]  

(2.78)

\[
\langle S_i \rangle_i = \frac{1}{V_{cell}} \int_{\sigma_i} (T_{3i} - T_i) n \, dS
\]  

(2.79)

By performing the integrals, we can derive

\[
\langle S_p \rangle_i = \frac{2\pi B_i^1}{V_{cell}} \cdot \frac{1 - k_i}{R_i + 1 - k_i}
\]  

(2.80)

\[
\langle S_i \rangle_i = \frac{2\pi B_i^1}{V_{cell}} \cdot \frac{R_i}{R_i + 1 - k_i}
\]  

(2.81)

By substituting the resultants in Eq. (2.77), the same formula is interestingly obtained as for a perfect interface

\[
k_e = 1 - 2\pi \frac{B_i^1 + B_i^2}{bE_{ext}} = 1 - \frac{2f_1y_1^1A_1^1 + 2f_2y_2^2A_2^2}{E_{ext}}
\]  

(2.82)
Chiew [1987], in studying the effect of resistance on the conductivity of two-phase dispersions made up of a random array of spheres, showed that there may be a critical situation in which the system does not sense the presence of the inclusions and behaves like a uniform matrix. A study into the behaviour of composites consisting of periodic and random arrays of uniform cylinders [Lu and Lin, 1995 and Lu and Song, 1996] and periodic arrays of spheres [Lu, 1997b and Cheng and Torquato, 1997] revealed that for all these cases, a critical situation occurs if \( R = k - 1 \). Here, the discussion will be extended to three-phase systems. Again, the extension is validated by comparing the results with those of two-phase systems [Lu and Lin, 1995] as shown in Table 2.5.

**Table 2.5** A comparison between the present results and those reported by Lu and Lin [1995] for the square array of the uniform cylinders.

</tbody>
</table>

As can be seen, the results of the two studies agree very well except for the case \( f = 0.785398, l/R = 0.0001 \). In the present study the number of terms included in the process of calculation was increased to more than 100 to see if the difference might be due to the number of terms. The obtained result was again about 0.14. Since the other values are greatly in agreement with those of Lu and Lin [1995], the suggested value for this case in this study is 0.14.

Figures 2.7 and 2.8 show the contours of the effective conductivity of the system for given conductivities. \( k_1 \) and \( k_2 \) were supposed to be 101 (this way, the logarithm of \( R_1 = R_2 = 100 \) would be an integer number) and volume fractions \( f_1 = f_2 = 0.4 \) in Fig. 2.7.
and \( f_1 = 0.4, f_2 = 0.2 \) in Fig. 2.8. As can be seen, the contours of the effective conductivity are similar to those in Figs. 2.4 and 2.6, and the effective conductivity of the materials can be highly affected because of the presence of interfacial resistance, and based upon the values of \( R_1 \) and \( R_2 \), the materials may exhibit a conductivity more, equal or even less than that of the matrix alone. Among the points rendering the presence of inclusions irrelevant, the case \( R_i = k_i - 1 (i=1,2) \) is of particular interest. In this situation, based on Eq. (2.75), the dipole polarisabilities are zero, which leads to \( B_1^i = B_1^2 = 0 \), and the state of the system resembles that of a system of perfect interfaces made up of inclusions the conductivity of which is equal to a unity. Therefore, it can be expected that changing the volume fractions, \( b \), does not alter the conductivity of the material from that of the matrix, which is correct.

![Figure 2.7](image_url)

**Figure 2.7** Contours of the effective conductivity for the imperfect interface case. \( f_1 = 0.4, f_2 = 0.4, k_1 = 101 \) and \( k_2 = 101 \).

Examination of Figs. 2.7 and 2.8 also shows that for any given values of \( R_i \), maximum there is a value of \( R_{2-\delta} \) at which the system yields a conductivity equal to a unity in the parallel or perpendicular directions. If, for a given \( R_i \) and \( R_{2-\delta} \), the system gives \( k_e = 1 \) in the parallel direction, it will not yield the same results for the perpendicular direction unless \( R_i = k_i - 1 (i = 1,2) \). Furthermore, in some cases, the value of \( R_i \) in the parallel direction is so large that
even when $R_{\eta_2} = 0$, the enhancing effect is not enough to increase the effective conductivity to the point at which the effect of the inclusions can be neglected. Inversely, in some cases, even when $R_{\eta_2}$ tends to infinity in the perpendicular direction, this does not reduce the conductivity of the system to that of the matrix.

Figure 2.8 Contours of the effective conductivity for the imperfect interface case. $f_1 = 0.4$, $f_2 = 0.2$, $k_1 = 101$ and $k_2 = 101$.

While the effect of both types of inclusion can be exactly neglected when $R_i = k_i - 1$ ($i=1,2$), in general, the effect of cylinders of type $i$ cannot be neglected when only $R_i = k_i - 1$. In other words, systems with $k_i = 1$, $R_i = 0$ and $k_i$, $R_i = k_i - 1$ are not equivalent if $R_{\eta_2} \neq k_{2-\eta_2} - 1$. Nevertheless, in this condition we find that $\gamma_i^t = 0$ and $B_i^t = 0$ but the terms $B_{2n-1}^t$ ($n > 1$) are not zero and are present in the procedure of the calculation of $B_{1}^{2-\eta_2}$, as is evident from Eq. (2.53). For a perfect contact case, all the terms $B_{2n-1}^t$ ($n > 1$) are zero and do not affect the value of $B_{1}^{2-\eta_2}$. The amount of discrepancy can only be numerically determined and depends on geometric considerations, resistance and the conductivity of the inclusions. A wide range of cases was tested in which $R_{\eta_2}$ increased from 0 to $\infty$. 
conductivities from 1 to 10000 and volume fractions from 0 to 0.45. The two-phase system can be simulated causing the conductivity of one of the phases to approach a unity. Figure 2.9 shows a sample of the calculations.

**Figure 2.9** The effective conductivity of the two- and three-phase systems. For the three-phase system, \( k_1 = 101, \ k_2 = 101, \ R_1 = 10 \) and \( R_2 = k_2 - 1 = 100 \). The two-phase system consists of a matrix and cylinders of type one with the same properties as those given in the three-phase case.

As can been seen, the results underestimate the conductivity of the two-phase system; however, for low volume fractions, the phase for which \( R_i = k_i - 1 \) can be easily replaced by the material of the matrix. This is also evident from relation (2.67), as it can be seen that when \( \gamma_i' = 0, \ k_e = 1 - 2f_{2-\delta,2}/(1 + c_i\gamma_i^{2-\delta,2}) \) is obtained. When \( f_i \) is increased, the error increases since the terms of higher orders play an important role in the response of the system; however, for all the cases studied, the relative error remains less than five percent in the parallel and seven percent in the perpendicular direction. Based on the results for cases \( b > \sqrt{3} \), smaller errors might be expected since the maximum values of \( f_1 \) and \( f_2 \) decrease.

Since the conductivity of the system is a continuous function of the parameters under study, for \( R_i < k_i - 1 \) a situation can be found in which a three-phase system gives exactly the same
conductivity as a two-phase system. This is always possible, since inclusions with conductivity greater than that of the matrix, boost the conductivity of the system. Figure 2.10 shows that a discrepancy from \( R_1 = 1 - k_1 \) causes a certain amount of error if the cylinders of the second type, for which \( R_2 = 1 - k_2 \), are replaced with the material of the matrix; therefore the value of \( R_2 \) has been reduced to obtain the conductivity of a two-phase system.

![Figure 2.10](image_url)

**Figure 2.10** Error encountered by replacing cylinders of type two, for which \( R_2 = k_2 - 1 \), with the material of the matrix and the calculated value for the resistance of the cylinders, in which the system gives exactly the conductivity of the two-phase system. \( f_1 = 0.45 \), \( f_2 = 0.45 \), \( k_1 = 1001 \), \( k_2 = 101 \).
3. COMPOSITE MATERIALS WITH PERIODIC ARRAYS OF ELLIPTICAL CYLINDERS

The studies pertaining to the determination of the effective transport properties of composites made up of elliptical cylinders are fewer in number and more recent than those for composites made up of circular cylinders. Zimmerman [1996] has studied the case of elliptical cylinders in the dilute limit using both the Maxwell and differential method and derived an expression for the effective conductivity of a material that has a very low volume fraction but a random orientation of elliptical cylinders. The case of periodic arrays has been considered by Lu [1994] who has applied the collocation scheme. The case of periodic arrangement has also been differently investigated by Nicorovici and McPhedran [1996] using Rayleigh’s method and in the context of dielectric permittivity. These authors had first formulated the lattice sums in polar coordinates which showed to be problematic and, therefore, later revised the formulation [Yardley et al., 1999] by calculating the lattice sums in elliptical cylinder coordinates. In this section Rayleigh’s method is developed to cover multi-coated elliptical cylinders (see also Moosavi and Sarkomaa [2003c]). It is tested whether the behaviour observed in circular cylinders can also be applied here. Clearly, the formulations can be used for any inspection related to the transport properties of composites with periodic arrays of coated elliptical cylinders.

The structure of the composites under study in this section is the same as that explained for the multiply coated circular cylinders in section 2.2. The only difference made here is to replace the circular cylinders with elliptical cylinders shown in Fig. 3.1. As can be seen, the distance between the two foci of the elliptical cylinders is equal to 2\( \rho \).

The most suitable coordinates for the presentation are elliptic cylindrical coordinates, which implies that

\[
x = \rho \cosh \mu \cos \theta
\]

\[
y = \rho \sinh \mu \sin \theta
\]
where $\theta$ is measured from the $x$-axis. As is customary in the analysis, an external field of magnitude $E_{ext}$ along the $x$-axis is applied in the negative direction. The temperature distribution [Nicorovici et al., 1996] inside the core, coating layers and matrix can be given in the form

$$T_i = C_0 + \sum_{l=1}^{\infty} \left[ C_l (\rho/2)^l \cosh l \mu \right] \cos l \theta + \left[ C_l' (\rho/2)^l \sinh l \mu \right] \sin l \theta \right]$$

$$T_i = A_0^i + \sum_{n=1}^{\infty} \left[ A_i^l (\rho/2)^l \cosh l \mu + B_i (2/\rho)^l e^{-l\mu} \right] \cos l \theta + \left[ A_i^n (\rho/2)^l \sinh l \mu + B_i^n (2/\rho)^l e^{-l\mu} \right] \sin l \theta \right]$$

$$T_i = A_0^i + \sum_{n=1}^{\infty} \left[ A_i^{(2n-1)} (\rho/2)^{2n-1} \cosh(2n-1) \mu \right] \cos(2n-1) \theta$$

In the above temperature functions, the terms $C_l'$, $A_l'$ and $B_l'$ cannot appear since the temperature is symmetric around $\theta = 0$. Also, the terms of even degree are excluded since the temperature is anti-symmetric around $\theta = \pi/2$; thus, $l = 2n - 1$ ($n = 1, \cdots, \infty$). Therefore, we have

$$T_i = A_0^i + \sum_{n=1}^{\infty} \left[ A_i^{(2n-1)} (\rho/2)^{2n-1} \cosh(2n-1) \mu + B_i^{(2n-1)} (2/\rho)^{2n-1} e^{-(2n-1)\mu} \right] \cos(2n-1) \theta$$

$$T_i = A_0^i + \sum_{n=1}^{\infty} \left[ A_i^{(2n-1)} (\rho/2)^{2n-1} \cosh(2n-1) \mu + B_i^{(2n-1)} (2/\rho)^{2n-1} e^{-(2n-1)\mu} \right] \cos(2n-1) \theta$$

Figure 3.1 The multicoated elliptical cylinder under study.
At the surface of the layers the following boundary conditions can be written:

\[ T_i = T_{i+1} \quad \text{and} \quad k_i \frac{\partial T_i}{\partial n} = k_{i+1} \frac{\partial T_{i+1}}{\partial n} \quad \mu = \mu_i \quad (i = 1, \ldots, N - 1) \] (3.7)

In this manner, \( A_{2n-1}', B_{2n-1}' \) and \( C_{2n-1}' \) can be related to each other. If Rayleigh’s method is performed, as explained in the previous chapter (see also Nicorovici et al. [1996]), the governing equations for the system can be given by the following equation:

\[ \xi^N_{2n-1} B^N_{2n-1} + \sum_{m=1}^{\infty} S_{2n-1,m} B^N_m = E_{\text{ext}} \delta_{n1}, \] (3.8)

where \( \xi^N_l \) \( (l = 2n - 1) \) can be derived by imposing the boundary conditions (3.7) as follows:

\[ \xi^j_l = \frac{e^{-\mu_{i-1}} (k_i - k_{i-1}) + 2 \xi_{i-1}^j (\rho / 2)^{2n} [k_i \cosh(\mu_{i-1}) + k_{i-1} \sinh(\mu_{i-1})]} {2 e^{-\mu_{i-1}} [k_i \sinh(\mu_{i-1}) + k_{i-1} \cosh(\mu_{i-1})] + 2 \xi_{i-1}^j (\rho / 2)^{2n} \sinh(2\mu_{i-1})(k_i - k_{i-1})} \times \frac{1}{(\rho / 2)^{2l} e^{\mu_{l-1}}} \] (3.9)

\( S_{lm} \) are elliptic lattice sums [Yardley et al., 1999] defined as:

\[ S_{lm} = \frac{1}{h_m} (2/\rho)^{\epsilon_m} \sum_{\eta \neq 0} \beta_{\epsilon_m} [(\alpha_j + i\eta_j)/\rho] \] (3.10)

where \( \alpha_j \) and \( \eta_j \) are coordinates of the center of the \( j \)th cylinder measured from the origin. \( h_m \) represents the Neumann symbol (1 for \( m = 0 \), 2 otherwise) and \( \beta_{\epsilon_m} (\zeta) \) is:

\[ \beta_{\epsilon_m} (\zeta) = (-1)^j h_m \sum_{h=0}^{\infty} \frac{(2h + l + m - 1)}{j! (h + m)! (l - 1)!} \times \exp[-(m + 2h + l) \cosh \epsilon \zeta] \times \] \[ _2 F_1 \left[ \begin{array}{c} 2h + m + l, 2h + m; l + 1; \exp(-2 \cosh \epsilon \zeta) \end{array} \right] \] (3.11)

Here, \( _2 F_1 \) represents Gauss’s hypergeometric function and is given by
Applying Green’s theorem will give the effective conductivity of the system as the following:

\[ k_e = 1 - \frac{2\pi B_1^N}{bE_{ext}} \]  

(3.13)

Let us test the correctness of the extension to a multiply coated case. Since as compared to the non-coated case [Yardley et al., 1999], only \( \xi_i \) has been changed, only this term is inspected here. One such inspection is to see whether (3.9) can be reduced to the corresponding relation of circular cylindrical inclusions in the limit, i.e. \( \rho \to 0 \) and \( \mu \to \infty \). Using

\[ \cosh x = \left( e^x + e^{-x} \right) / 2 \]

and

\[ \sinh x = \left( e^x - e^{-x} \right) / 2 \]

we get

\[ \xi_i = \frac{(k_i - k_{i-1}) + \xi_{i-1}^{-1} (\rho / 2)^{2i} k_i (e^{2\mu_{i-1}} - 1) + k_{i-1} (e^{2\mu_i} - 1)}{k_i (1 - e^{-2\mu_{i-1}}) + k_{i-1} (1 + e^{-2\mu_i}) + \xi_{i-1}^{-1} (\rho / 2)^{2i} (e^{2\mu_{i-1}} - e^{-2\mu_i}) (k_i - k_{i-1})} \times \frac{1}{(\rho / 2)^{2i} e^{2\mu_{i-1}}} \]

(3.14)

At the limit, we have

\[ \lim_{\rho \to 0} \frac{e^{\mu_i}}{2} = a_i \]

[Meixner and Schäfke, 1954]; therefore, the following relation can be obtained:

\[ \xi_i = \frac{k_i - k_{i-1} + (k_i + k_{i-1}) \xi_{i-1}^{-1} a_i^{2i} - 1}{k_i + k_{i-1} + (k_i - k_{i-1}) \xi_{i-1}^{-1} a_i^{2i}} \times \frac{1}{a_i^{2i}} \]

(3.15)

which is exactly the relation derived for the case of multiply coated circular cylinders. Also, for the cases in which the coating layer \( i-1 \) is perfectly insulating or conducting, we derive

\[ \xi_{i} = \frac{1}{(\rho / 2)^{2i} (e^{2\mu_{i-1}} - 1)} \]  

\( (k_{i-1} = 0) \)

(3.16)
As can be seen, there is no information on the layers below the layer \( i-1 \), which means that the layer \( i-1 \) intersects the relation between the layer \( i \) and the layers below the layer \( i-1 \). Note that at the limit, (3.16) and (3.17) are reduced to \( \xi_{i}^{i} = 1/a_{i-1}^{2i} \) and \( \xi_{i}^{i} = -1/a_{i-1}^{2i} \), respectively. The above tests give the measures of the correctness of the extension in the \( x \)-direction. Similar to the discussion outlined in chapter 2, an extension in the perpendicular direction can also be readily performed.

Next, let us see whether the behaviour explained for multiply coated circular cylinders in the case \( \varepsilon_{i} + \varepsilon_{i-1} = 0 \) can also be applied here. This can be done again by inspecting \( \xi_{i}^{i} \). By comparing (3.14) and (3.15), it is found that the inverse of (3.15), \( \varepsilon_{i} = -\varepsilon_{i-1} \), is not explicit in (3.14) and, thereby, considering that \( \varepsilon_{i} = -\varepsilon_{i-1} \) will not lead to any specific result. Therefore, the above-mentioned behaviour for circular cylinders cannot be applied to an arbitrary coated cylindrical system. Figure 3.1(a, b) shows that for this case, changing the dielectric constant of the coating layer from \( \varepsilon_{2} = \varepsilon_{1} \) to \( \varepsilon_{2} = -\varepsilon_{1} \) alters the field through the matrix.

\[
\xi_{i}^{i} = -\frac{1}{(\rho/2)^{2i}(\varepsilon^{2i})^{i-1} + 1} \quad (k_{i-1} = \infty)
\]

\end{figure}
4. KELLER’S THEOREM

The Keller reciprocal relation [Keller, 1964] has shown its usefulness in many studies and is worth being examined here. Keller showed that for a composite material consisting of a matrix and cylinder-shaped inclusions arranged in a regular array, the following relation is obtained:

\[ k_e(k_1, k_2) \times k'_e(k_2, k_1) = k_1k_2, \]  

(4.1)

where \( k_e \) and \( k'_e \) represent the conductivity of the system in the symmetry axes \( x \) and \( y \), respectively. Keller further claimed that the above-mentioned relation will work for composites made up of randomly arranged cylindrical inclusions. Mendelson [1974] later showed that this is indeed valid, considering that \( x \) and \( y \) are now the principal axes of the system. If the medium is statistically isotropic, relation (4.1) can be rewritten as

\[ k_e(k_1, k_2) = k_1k_2 \]  

(4.2)

Furthermore, if the phases are statistically equivalent (interchangeable), we obtain

\[ k_e(k_1, k_2) = k_e(k_2, k_1) = \sqrt{k_1k_2} \]  

(4.3)

The above relation is of interest since it is geometry-independent and gives in a very simple form the exact effective conductivity of systems for which deriving the effective transport properties requires a considerable mathematical effort (for example, the square checkerboard). More recently, Lu [1999] has considered composites with regular arrays of multicoated cylinders and derived the following:

\[ k_e(k_1, \ldots, k_N) \times k'_e(1/k_1, \ldots, 1/k_N) = 1 \]  

(4.4)

For multiphase non-coated composites, Fel et al. [2000] have also obtained the same relation. Here, extending Mendelson’s methodology, the elegant strategy behind the relations will be
shown. The technique is simple and uses the fact that any two-dimensional divergence-free field, when rotated locally at each point by 90°, produces a curl-free field and vice versa [Milton, 1988]. Composites made up of coated cylindrical inclusions are considered here, although with slight changes the discussion can be extended to multiphase composites made up of non-coated inclusions.

Consider a composite material consisting of a matrix and a series of cylinder-shaped inclusions that are placed in a random arrangement inside the matrix. The inclusions are uniform and multicoated with the property of the dispersed layers and the matrix being equal to \( k_1, \ldots, k_{N-1} \) and \( k_N \) (we can consider \( k_N = 1 \)), respectively. Suppose that the system is statistically homogeneous, \( x \) and \( y \) are the principal axes and the potential functions, \( T'_i, \ldots, T'_N \), are the solutions of the Laplace equation \( (\nabla^2 T = 0) \) in the system. Here, \( j \) refers to \( j \)th cylinder. Therefore, on the surface between the layers, we have \( \partial T'_i / \partial \ell = \partial T'_i / \partial \ell \left( T'_i = T'_{i+1} \right) \), where \( \ell \) is the distance measured along the interfaces and \( k_i, \partial T'_i / \partial n = k_{i+1}, \partial T'_{i+1} / \partial n \), where \( n \) is the normal outward direction to the interfaces. If a series of functions \( \psi_i, (i = 1, \ldots, N) \) is defined, in which \( \nabla \times (\psi_i k) = -k \nabla \psi_i = k_i \nabla T'_i \), we have \( \partial \psi_i / \partial y = k, \partial T'_i / \partial x \) and \( \partial \psi_i / \partial x = -k, \partial T'_i / \partial y \); therefore, \( \psi_i \) satisfies the Laplace equation in the layers \( i \) of cylinder \( j \). The first boundary condition for \( T'_i \) will lead to finding \( (1/k_i) \partial \psi_i / \partial n = (1/k_{i+1}) \partial \psi_{i+1} / \partial n \) and the second one will give \( \partial \psi_i / \partial \ell = \partial \psi_i / \partial \ell \) \( (\psi_i = \psi_{i+1}) \). As a result we have a function \( \psi \), which is the solution of the Laplace equation in the same composite but with the properties of the phases equal to \( 1/k_1, \ldots, 1/k_N \). Based on definition of the effective conductivity, we obtain

\[
k_e (k_1, \ldots, k_N) \times k_e (1/k_1, \ldots, 1/k_N) = \frac{\int_V k \nabla T \, dv}{\int_V \nabla T \, dv} \times \frac{\int_V k \nabla \psi \, dv}{\int_V \nabla \psi \, dv} \tag{4.5}
\]
Here, \( V \) is the volume containing a sufficient number of inclusions. The analysis is started by deriving \( \int_V \nabla T \, dv \) and \( \int_V k \nabla T \, dv \). Getting help from Green’s first identity [Spiegel, 1968] it is found that

\[
\int_V \nabla T \, dv = \oint_\sigma T \, ds = \oint_\sigma T_n \, ds + \oint_\sigma T_y \, ds = \oint_\sigma T_n \, ds
\]

(4.6)

where \( \sigma \) is the boundary surface of the volume \( V \). Here \( \oint_\sigma T_y \, ds \) has been ignored because of the selection of the principal axes. Furthermore, we have [Spiegel, 1968]:

\[
\oint_\sigma T_n \, ds
\]

Using this property, we obtain

\[
\int_V \nabla \times (\psi k) \, dv = \int_\sigma d s \times (\psi k)
\]

(4.7)

Using this property, we obtain

\[
\int_V k \nabla T \, dv = \oint_\sigma \nabla \times (\psi k) \, dv = \oint_\sigma \psi n_s \, ds - \oint_\sigma \psi m_y \, ds = \oint_\sigma \psi n_s \, ds
\]

(4.8)

Here again, the selection of the principal axes has implied that \( \oint_\sigma \psi n_s \, ds = 0 \).

Now, \( \int_V \nabla \psi d v \) and \( \int_V k \nabla \psi d v \) are studied. Using Green’s first identity and applying \( \oint_\sigma \psi n_s \, ds = 0 \), we obtain

\[
\int_V \nabla \psi d V = \oint_\sigma \psi n_s \, ds + \oint_\sigma \psi m_y \, ds = \oint_\sigma \psi n_s \, ds
\]

(4.9)

Since \( \nabla \psi_i / d = -k \times (k, \nabla T_i / d) \) and \( \oint_\sigma T_n \, ds = 0 \), also the following can be obtained:

\[
\int_V k \nabla \psi d v = \int_V k \times \nabla T d v = -\int_V \nabla \times (T k) \, dv = -\oint_\sigma T n_s \, ds + \oint_\sigma T n_y \, ds = \oint_\sigma T n_s \, ds
\]

(4.10)
Here, the property given in (4.7) has been used. Substituting (4.6), (4.8), (4.9) and (4.10) in (4.5), we can derive

\[ k_e(k_1, \ldots, k_N) \times k'_e(1/k_1, \ldots, 1/k_N) = 1 \]  

(4.11)
5. COMPOSITE MATERIALS WITH PERIODIC ARRAYS OF SPHERES

The first composites studied by researchers to derive the effective transport properties were composites with spherical inclusions, as is Maxwell’s case studies [1873] (see Moosavi et al. [2002b] for a review). In this chapter, these composites are studied in cases where the inclusions are placed in a periodic arrangement. The terminology used for the presentation is the same as that given by Cheng and Torquat [1997] who considered cases in which the unit cell of the system was a cube. In this chapter a more general state will be considered in which the unit cell of the system is a rectangular prism. In specific cases, the discussion can be reduced to those considered by the above authors. Also formulations for the case of multiphase systems (coated and non-coated) will be developed below. It should be noted that the case of composites with periodic spheres in a rectangular order was first investigated by Rayleigh [1892].

5.1 The case of a two-phase composite with uniform and solid spheres

Let us consider a composite material with a unit cell in the shape of a rectangular prism in which a sphere is placed at the centre and possibly at each corner or face of the unit cell. For greater generality, the sides of the unit cell will be considered \( b, c \) and a unity in the \( x-, y- \) and \( z- \) directions of the cartesian coordinates which has been placed at the centre of a sphere situated at the centre of the unit cell. Also, the continuous medium is supposed to have a unit conductivity. The radius of the spheres is denoted by \( a \) and the conductivity by \( k \). Assuming that \( b=c=1 \), the unit cell of the system would be a cube, and simple cubic, body-centred and face-centred structures can be constructed.

As is clear, in general, the system is anisotropic; therefore, three different conductivities may be expected for the system in the \( x-, y- \) and \( z- \) directions. Since deriving the conductivity of the system in these directions is similar, the conductivity of the system is only derived in one direction, namely the \( x- \) direction. To perform this, a uniform field of magnitude \( E_{ext} \) is applied externally along the \( x- \) axis of the system in the negative direction. If a spherical coordinate
\((r, \theta, \phi)\) is set at the origin, in which \(\theta\) is measured from the \(x\)-axis and \(\phi\) from the \(xy\) plane, the temperature inside the sphere and the matrix in terms of spherical harmonics can be given by

\[
T_1 = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} C_{lm} r^l Y_{lm}(\theta, \phi) \tag{5.1}
\]

\[
T_2 = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} (A_{lm} r^l + B_{lm} r^{-l-1}) Y_{lm}(\theta, \phi), \tag{5.2}
\]

where \(C_{lm}, A_{lm}\) and \(B_{lm}\) are unknowns to be determined and \(Y_{lm}(\theta, \phi)\) is a spherical harmonics of the order \((l,m)\) defined as:

\[
Y_{lm}(\theta, \phi) = \frac{(l-m)!}{(l+m)!} P_l^m(\cos \theta) e^{im\phi} \tag{5.3}
\]

On the surface of the spheres, we can write down the following continuity relations can be written:

\[
T_1 = T_2, \quad k \frac{\partial T_1}{\partial r} = \frac{\partial T_2}{\partial r} \quad r = a, \tag{5.4}
\]

which lead to

\[
A_{lm} = \frac{B_{lm}}{\gamma_l a^{2l+1}} = \xi_l B_{lm} \tag{5.5}
\]

\[
C_{lm} = \frac{B_{lm}}{\chi_l a^{2l+1}}, \tag{5.6}
\]

where

\[
\gamma_l = \frac{1-k}{k + (l+1)/l} \tag{5.7}
\]
The temperature around the origin, when the origin is not included, can be considered due to
terms originating at infinity and at the other lattice sites (see section 2.1); therefore we can write

\[ \chi_i = \frac{1-k}{(2l+1)/l} \]  

(5.8)

\[ \sum_{l=0}^{\infty} \sum_{m=-l}^{l} A_{lm} r^l Y_{lm}(\theta, \phi) = E_{ext} x + \sum_{l=0}^{\infty} \sum_{j=-l}^{l} \sum_{h\neq 0}^{\infty} B_{ij} Y_{ij}(\theta, \phi_h) \]  

(5.9)

where \((r_h, \theta_h, \phi_h)\) is the spherical coordinate of a point measured from the lattice point \(h\).

Using Eq. (5.5) and considering that \(x = r\cos\theta = Y_{10}(\theta, \phi)\), the above equation can be written in the following form:

\[ \sum_{l=0}^{\infty} \sum_{m=-l}^{l} B_{lm} Y_{lm}(\theta, \phi) = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} E_{ext} \delta_{ml} Y_{lm}(\theta, \phi) + \sum_{l=0}^{\infty} \sum_{j=-l}^{l} \sum_{h\neq 0}^{\infty} B_{ij} Y_{ij}(\theta, \phi_h) \]  

(5.10)

As can be seen, the left-hand side and the first part of the right-hand side are given on the
basis of the coordinate situated at the origin, but the second part on the right-hand side has
been expressed on the basis of the coordinates placed at the centre of the other spheres. To
proceed, all the terms have to presented on the basis of the coordinates situated at the origin.

For this purpose, the general form of a theorem on spherical harmonics can be used, well
known as the addition theorem [McKenzie et al, 1978; Greengard, 1988]. On the basis of this
theorem, we have

\[ \frac{Y_{ij}(\theta, \phi_h)}{r_{ij}^{l+1}} = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} (-1)^l J_{m}|_{l+i+m}^{l-i-m} Y_{l+i,j-m}(\theta, \phi_0) \frac{Y_{lm}(\theta, \phi)}{r_{ij}^{l+1}} \]  

(5.11)

where
\[ J_{m}^{j} = \begin{cases} (-1)^{\min(|m|,|j|)} & \text{if } m \cdot j > 0, \\ 1 & \text{otherwise} \end{cases}, \quad \eta^{j}_{l} = \sqrt{\left( l + i \right)} \]  
(5.12)

Here, \((r_{h0}, \theta_{h0}, \phi_{h0})\) expresses the centre of the \(h\)th sphere measured from the origin. By substituting the above relation in (5.10), we can obtain

\[
\sum_{l=0}^{\infty} \sum_{m=-l}^{l} \frac{B_{lm}}{Y_{l}(\alpha)} r^{l} Y_{lm}(\theta, \phi) = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} E_{\text{ext}} \delta_{l} \delta_{m0} r^{l} Y_{lm}(\theta, \phi) + 
\sum_{l=0}^{\infty} \sum_{m=-l}^{l} \sum_{i=0}^{\infty} \sum_{j=-i}^{i} (-1)^{j} J_{m}^{j} r^{l} \eta^{l}_{l+m} \eta^{l}_{l-m} B_{y} Y_{lm}(\theta, \phi) \]  
(5.13)

If the lattice sums for an array of spherical inclusions are defined as

\[ S_{lm} = \sum_{h=0}^{\infty} \frac{Y_{lm}(\theta_{h0}, \phi_{h0})}{r_{h0}} \]  
(5.14)

Eq. (5.13) can be given as

\[
\sum_{l=0}^{\infty} \sum_{m=-l}^{l} \frac{B_{lm}}{Y_{l}(\alpha)} r^{l} Y_{lm}(\theta, \phi) = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} E_{\text{ext}} \delta_{l} \delta_{m0} r^{l} Y_{lm}(\theta, \phi) + 
\sum_{l=0}^{\infty} \sum_{m=-l}^{l} \sum_{i=0}^{\infty} \sum_{j=-i}^{i} (-1)^{j} J_{m}^{j} r^{l} \eta^{l}_{l+m} \eta^{l}_{l-m} S_{l+j} B_{y} Y_{lm}(\theta, \phi) \]  
(5.15)

Since the above equation is valid for arbitrary values of \(r, \theta\) and \(\phi\) and spherical harmonics are linearly independent, the terms of the left- and right-hand sides of the above equation can be equated for a specific value of \(l\) and \(m\), i.e.,

\[
\frac{B_{lm}}{Y_{l}(\alpha)} = E_{\text{ext}} \delta_{l} \delta_{m0} + \sum_{i=0}^{\infty} \sum_{j=-i}^{i} (-1)^{j} J_{m}^{j} r^{l} \eta^{l}_{l+m} \eta^{l}_{l-m} S_{l+j} B_{y} \]  
(5.16)
Now, let us reconsider the structure under study and also the temperature functions given in (5.1) and (5.2). An examination reveals that $l (i)$ has to be an odd number because of the skew symmetry of the temperature around $\theta = \pi/2$. Also, $m$ must be considered as an even number because the temperature is symmetric around $\phi = \pi/2$. Furthermore, in the case $c=1$, $m (j)$ should be considered a multiple of 4; therefore, $(-1)^j = -1$ and $J_m = 1$. After performing the necessary changes to bring the summation from negative $j$ to positive values, Eq. (5.10) can be rewritten as follows:

$$\frac{B_{m-n,1-m}}{\gamma_{m-1}a^{4n-1}} + \sum_{i=0}^{\infty} \sum_{j=0}^{2i-1} h_j \left( \frac{2i-1-j}{2n+2i-2j+m} \right) B_{i,1-j} = E_{ex} \delta_{n0} \delta_{m0}$$

(5.17)

Here $h_j$ is the Neumann symbol ($1$ for $j=0$, $2$ otherwise). This symbol was added because for $j = 0$, the results of the summation is twice the one derived from Eq. (5.16). Since $Y_s(-\theta, \phi) = Y_s(\theta, \phi)$, where the asterisk stands for a complex conjugation, the sign of $m$ in $S_{lm}$ is limited to positive values.

As explained in chapter 2, considering a sufficient number of unknowns will lead to the required result. Based on reports given by McPhedran and McKenzie [1978] and McKenzie et al. [1978] with 50 zonal unknowns together with azimuthal terms, the results are reasonable for volume fractions up to 0.523 (SC), 0.677 (BCC) and 0.733 (FCC) for any values of the conductivity of the inclusions.

5.1.1 Determining the effective conductivity of the system

In the same terminology used for the solid cylinder, for the average heat flux and temperature gradient we can write

$$\langle F \rangle = M \langle S_p \rangle - \langle \nabla T \rangle$$

(5.18)

where $M$ is the number of spheres in the unit cell and
where \( V_1 \) is the volume of the sphere. Taking into consideration the temperature profiles given in Eqs. (5.1) and (5.2) and using orthogonality properties of spherical harmonics, we obtain

\[
\langle S_p \rangle = \frac{1-k}{V_{cell}} \int \nabla T \, dV
\]

(5.19)

\[
\langle \nabla T \rangle = \frac{1}{V_{cell}} \int_{V_{cell}} \nabla T \, dV,
\]

(5.20)

Here, \( \sigma_1 \) represents the surface of the sphere. By substituting (5.21) in (5.18) and considering that \( \langle \nabla T \rangle = E_{ext} \) and \( V_{cell} = bc \), the final result for the effective conductivity can be given as

\[
k_e = 1 - \frac{4M_1 B_{1,0}}{bc E_{ext}}
\]

(5.22)

### 5.1.2 Explicit forms for the effective conductivity

Applying the truncation order 4 allows the solution of Eq. (5.17) to be expressed as follows:

\[
k_{eff} = 1 - \frac{3f}{D},
\]

(5.23)

where

\[
D = 1/\gamma_1 + f - c_2 \gamma_2 f^{10/3} \frac{1-c_4 \gamma_3 f^{11/3}}{1+c_2 \gamma_2 f^{7/3}} - c_3 \gamma_3 f^{14/3} - c_4 \gamma_4 f^6 - c_5 \gamma_5 f^{22/3} + O(f^{25/3})
\]

(5.24)

The numerical constants, for the case in which the unit cell is a cube, are given in [Sangani and Acrivos, 1983] and are shown below in Table 5.1.
Table 5.1 The numerical constants in the explicit expression (5.24).

5.2 The case of a periodic array of coated spheres

The present author has recently reported a study performed on composites with cubic arrays of multi-coated spheres [Moosavi et al., 2002b]. For these composites, the changes required to develop the above procedures for two-phase systems in the case of multi-coated systems will be discussed below. The conductivity and radii of the core and coating layers are denoted by $k_{i, \cdots, k_{N-1}}$ and $a_{i, \cdots, a_{N-1}}$, respectively. The temperature functions inside the layers can be given by

$$T_i = \sum_{n=0}^{\infty} \sum_{m=0}^{2n-1} C_{2n-1,m} r^{2n-1} Y_{2n-1,m} (\theta, \phi)$$  \hspace{1cm} (5.25)

$$T_i = \sum_{n=0}^{\infty} \sum_{m=0}^{2n-1} \left( A_{2n-1,m}^i r^{2n-1} + B_{2n-1,m}^i r^{-2n} \right) Y_{2n-1,m} (\theta, \phi) \quad (i = 2, \ldots, N)$$  \hspace{1cm} (5.26)

At the surface of the core and coating layers, the boundary conditions

$$T_i = T_{i+1}, \quad k_i \partial T_i / \partial r = k_{i+1} \partial T_{i+1} / \partial r \quad r = a_i \quad (i = 1, \ldots, N - 1)$$  \hspace{1cm} (5.27)

are applied, whence we can be related the coefficients, i.e.,

$$A_{2n-1,m}^i = \frac{B_{2n-1,m}^i}{\gamma_{2n-1} a_{i-1}} = \xi_{2n-1} B_{2n-1,m}^i,$$  \hspace{1cm} (5.28)

where
An equation of type (5.9) can be written for this system, i.e.,

$$\sum_{n=0}^{\infty} \sum_{m=0}^{2n-1} A_{2n-1,m} r^{2n-1} Y_{2n-1,m}(\theta, \phi) = E_{\text{ext}} x + \sum_{i=0}^{\infty} \sum_{j=0}^{2i-1} \sum_{k=0}^{2j-1} B_{2i-1,j}^{N} \frac{Y_{2i-1,j}(\theta, \phi)}{r_{h}^{2j}}$$  

(5.30)

After performing the other required steps, the final equation is

$$\frac{B_{2n-1,m}^{N}}{\gamma_{2n-1}^{N} a_{n}^{4n-1}} + \sum_{n=0}^{\infty} \sum_{m=0}^{2n-1} h \left( n_{2n-1+m}^{2n-1-j} n_{2n-1-m}^{2n-1+j} S_{2n+2j-2,j-m} + n_{2n-1+m}^{2n-1-j} n_{2n-1-m}^{2n-1+j} S_{2n+2j-2,j+m} \right) B_{2n-1,j}^{N} = E_{\text{ext}} \delta_{n1} \delta_{m0}$$  

(5.31)

By applying the same method used for the case of solid spheres, the effective conductivity of the system again can again be given by

$$k_{e} = 1 - \frac{4MB_{1}^{N}}{bcE_{\text{ext}}}$$  

(5.32)

### 5.2.1 Comparison between the behaviour of coated spheres and circular cylinders

In this chapter the focus is shifted back to the general state, assuming that the transport property can be negative or positive. If one layer \((2 \leq i \leq N-1)\) is perfectly conducting \((\varepsilon_{i} = \infty)\) or non-conducting \((\varepsilon_{i} = 0)\), the layers under this layer will not contribute to the effective property of the system. These results can also be easily seen in Eq. (5.29), where the multipolar polarisability for the cases in question would be \(-1\) and \(1\), respectively. Furthermore, two spheres with the same property can be unified and considered as being a unit layer, which is obvious and can be confirmed from Eq. (5.29).
In the section on cylindrical inclusions, the strange behaviour of coated cylinders when \( \varepsilon_i + \varepsilon_{i-1} = 0 \) was studied. Here, the aim is to find out whether the same behaviour can be observed for the case of multicoated spheres. Nicorovici et al. [1995] found that the case of singly coated spheres did not exhibit the same behaviour as that of coated cylinders. The reason is clear when it is kept in mind that all the behaviour was based on the mathematical expression for multipolar polarisability. Here, \( \gamma_{2n-1}^1 \) is a function of \( n \) and because of this, the results are not the same. A careful examination of this case, however, shows that by the first order, the cases \( \varepsilon_2 = -0.5\varepsilon_1 \) and \( \varepsilon_2 = \varepsilon_1 \) yield the same effective transport property; however, the inspection of (5.29) shows that even this result cannot be extended to the case of multicoated spheres. This makes sense physically, since the successive application of \( \varepsilon_i = -0.5\varepsilon_{i-1} \) to infinitely coated layers causes the property of the outermost coating layer to approach zero, and this case exhibits the behaviour of non-conducting spheres of radius \( a_N \) \( (N \to \infty) \) and not of spheres that have a property equal to \( \varepsilon_i \) with a radius of \( a_N \).

### 5.3 Three-phase non-coated spheres

In accordance with the three-phase case explained for circular cylinders, here a composite is considered in which the unit cell of the system is a rectangular prism with a sphere of type one at the center and a sphere of type two at each corner. The formulations can be readily developed for other structures. It should be noted that when \( b=c=1 \), the structure is CsCl that has been studied by McPhedran [1983]. For this case, the temperature of the phases and the matrix can be expressed as

\[
T_j = \sum_{n=1}^{\infty} \sum_{m=0}^{2n-1} C_{2n-1,m}^j r^{2n-1}Y_{2n-1,m}(r,\theta) \tag{5.33}
\]

\[
T_{3,i} = \sum_{n=1}^{\infty} \sum_{m=0}^{2n-1} \left( A_{2n-1,m}^i r^{2n-1} + B_{2n-1,m}^i r^{-2n+1} \right) Y_{2n-1,m}(r,\theta), \tag{5.34}
\]

where \( i \) can be either 1 or 2 showing the sphere type. As can be seen, the non-symmetry of the temperature around \( \theta = \pi/2 \) has been taken into account. Because of the symmetry of the
temperature around, also \( m \) will be considered to be an even number in general and for the case \( c=1 \), a multiple of 4. The boundary conditions are of the following shape:

\[
T_i = T_{3i}, \quad k_i \frac{\partial T_i}{\partial r} = \frac{\partial T_{3i}}{\partial r} \quad \text{on} \quad r = a_i
\]  

(5.35)

Therefore, for the coefficient of the temperature functions, we obtain

\[
A_{2n-1}^i = \frac{B_{2n-1}^i}{\gamma_{2n-1}^i \alpha_i} \quad \text{(5.36)}
\]

\[
C_{2n-1}^i = \frac{B_{2n-1}^i}{\chi_{2n-1}^i \alpha_i^4} \quad \text{(5.37)}
\]

where

\[
\gamma_{2n-1}^i = \frac{1-k_i}{k_i + 2n/(2n-1)} \quad \text{(5.38)}
\]

\[
\chi_{2n-1}^i = \frac{1-k_i}{(4n-1)/(2n-1)} \quad \text{(5.39)}
\]

By separating the effect of the inclusions of type one and two, we get

\[
\sum_{n=0}^{\infty} \sum_{m=0}^{2n-1} A_{2n-1,m}^i r^{2n-1} Y_{2n-1,m}(\theta, \phi) = \frac{E_0 r}{4n+1} \cos \theta + \sum_{n=0}^{\infty} \sum_{m=0}^{2n-1} B_{2n-1,m}^i r^{2n-1} Y_{2n-1,m}(\theta, \phi) + \sum_{n=0}^{\infty} \sum_{m=0}^{2n-1} \sum_{h=0}^{2n-1} B_{2n-1,m}^i r^{2n-1} Y_{2n-1,m}(\theta_h, \phi_h) \quad \text{(5.40)}
\]

By following the same methodology as given for solid spheres we obtain the following linear system is obtained:

\[
\frac{B_{2n-1,m}^i}{\gamma_{2n-1}^i \alpha_i^{4n+1}} + \sum_{l=0}^{\infty} \sum_{j=0}^{2l+1} \frac{h_j}{2} \left[ \mathbf{n}_{2n-1+m}^{2l+1+j} \left( S_{2n-2l-2-j}^1 B_{2l+1-j}^i + \frac{S_{2n-2l-2-j}^2}{m} B_{2l+1-j}^{2-2\delta} \right) + \mathbf{n}_{2n-1+m}^{2l+1+j} \left( S_{2n+2l-2-j+m}^1 B_{2l+1-j}^i + \frac{S_{2n+2l-2-j+m}^2}{m} B_{2l+1-j}^{2-2\delta} \right) \right] = E \delta_m \delta_{l0} \quad \text{(5.41)}
\]
where \( S'_{nm} \) are the lattice sums over the spheres of type \( i \). For a three-phase case, the volume averaged flux and temperature are related to each other by

\[
\langle \mathbf{F} \rangle = \langle \mathbf{S}_p \rangle_1 + \langle \mathbf{S}_p \rangle_2 - \langle \nabla T \rangle \quad (5.42)
\]

\[
\langle \mathbf{S}_p \rangle_i = \frac{1-k_i}{V_{\text{cell}}} \int_{V_i} \nabla T_i dV \quad (5.43)
\]

After performing the integrals in the same manner as that explained for uniform spheres, we obtain

\[
k_e = 1 - \frac{2\pi (B_1^i + B_2^j)}{bcE_{\text{ext}}} \quad (5.44)
\]

For the case of circular cylindrical inclusions, it was shown that the composite can be perfectly conducting in one direction and non-conducting in the other. However, for the case of spherical inclusions, this behavior does not hold true and these composites cannot be non-conducting since heat can pass through the gaps between the spheres. Furthermore, the Keller theorem is not valid here, and thus, for the case of mono-sized spherical inclusions, when \( k_1 = 1/k_2 \), the effective conductivity of the system is not equal to that of the matrix.

### 5.3.1 The case of an imperfect interface

The boundary conditions, including the effect of interfacial resistance, are of the following shape:

\[
\frac{k_i}{R_i a_i} (T_i - T_{3,i}) = -k_i \frac{\partial T_i}{\partial r} = - \frac{\partial T_{3,i}}{\partial r} \quad \text{on} \quad r = a_i \quad (5.45)
\]

with

\[
A^i_{2n-1} = \frac{B^i_{2n-1}}{\gamma_{2n-1} a_i^{4n-2}} \quad (5.46)
\]

\[
C^i_{2n-1} = \frac{B^i_{2n-1}}{\chi_{2n-1} a_i^{4n-2}} \quad (5.47)
\]

where
\[
\gamma_{2n-1}^i = \frac{1 - k_i + R_i (2n - 1)}{2n/(2n - 1) + k_i + 2n R_i} \quad \chi_{2n-1}^i = \frac{1 - k_i + R_i (2n - 1)}{(4n - 1)/(2n - 1)}
\] (5.48)

For this case, the relation between the volume averaged flux and temperature would be

\[
\langle F \rangle = \langle S_P \rangle_1 + \langle S_P \rangle_2 + \langle S_I \rangle_1 + \langle S_I \rangle_2 - \langle \nabla T \rangle,
\] (5.49)

where

\[
\langle S_P \rangle_i = \frac{1 - k_i}{V_{cell}} \int_{V_i} \nabla T \cdot dV
\] (5.50)

\[
\langle S_I \rangle_i = \frac{1}{V_{cell}} \int_{S_i} (T_{3i} - T_i) n dS,
\] (5.51)

from which we obtain

\[
\langle S_P \rangle_i = \frac{2\pi B_i^i}{V_{cell}} \cdot \frac{1 - k_i}{R_i + 1 - k_i} i
\] (5.52)

\[
\langle S_I \rangle_i = \frac{2\pi B_i^i}{V_{cell}} \cdot \frac{R_i}{R_i + 1 - k_i} i
\] (5.53)

By substituting the resultants in Eq. (5.48), we obtain a relation that resembles relation (5.44).

As is clear from (5.48), the critical resistance in the case of composites with mono-sized uniform spherical inclusions can be derived using the same formula as the cylindrical inclusions, i.e., \( R = k - 1 \). Furthermore, because of the mathematical similarity between (5.41) and (2.54), similar results can be expected as in the case of three-phase composites made up of cylindrical inclusions. Therefore, the effect of spherical inclusions of type \( i \) in any direction of the calculation of the effective conductivity can be neglected by adjusting the interfacial resistance in the range \( R_i \leq k_i - 1 \).
6. LATTICE SUMS

The problem of calculating lattice sums arises when studying a variety of phenomena in various branches of science including materials science. These sums have the following form for fiber composites:

\[ S_n = \sum_{\omega \in \Lambda_2} \frac{1}{\omega^n}, \quad (6.1) \]

where \( \Lambda_2 = \{ l_1 b + i l_2 \mid l_1, l_2 \in \mathbb{Z}, l_1 b + i l_2 \neq 0 \} \). In three-dimensions, we also have

\[ S_{nm} = \sum_{j \in \Lambda_3} \frac{Y_{nm}(\theta_j, \phi_j)}{r_j^{n+1}}, \quad (6.2) \]

where \( \Lambda_3 = \{ (l_1 b, l_2 c, l_3) \mid l_i \in \mathbb{Z}, (l_1 b, l_2, l_3) \neq (0,0,0) \} \). Here, \( (r_j, \theta_j, \phi_j) \) expresses the position of a point in spherical coordinates. In the thesis the main interest is in calculating \( S_n \) and \( S_{nm} \) for \( n \geq 2 \) and \( m \geq 0 \). For this purpose, the direct summation method can be used, although the results will converge very slowly. For this reason, many algorithms have been developed for the rapid and highly accurate calculation of lattice sums [Greengard and Rokhlin, 1997; Helsing, 1994; Movchan et al., 1997 and Huang, 1999] some of these algorithms will be explained in this section.

6.1 Integral representation of the lattice sums

Huang [1999] has shown that the problem of calculating lattice sums can be reduced to the one of calculating integrals. The mathematical basis for this method is the plane-wave representation of each pole and analytically summing up the resulting geometric series. Here, the method for a rectangular array of cylinders with periodicity equal to \( b \) and a unity in the \( x \)- and \( y \)-directions, respectively, is explained. For an arbitrary point in the complex plane \((z = x + iy)\), depending on the region in which the point is situated, we can write
where \( n = 1, \ldots, \infty \). The reason for the case \( n=1 \) is clear, as a simple analytical integration of the right-hand side yields the left-hand expression. For the other values of \( n \), it is possible to differentiate both sides of the case \( n=1 \) with respect to \( z \), \( n \) times, in order to obtain the above relations. To calculate the lattice sums given in Eq. (6.1), the lattice is divided into four regions, as depicted in Fig. (6.1).

![Figure 6.1](image-url)

**Figure 6.1** The methodology used for calculating the lattice sums

As can be seen for regions 1 to 4, we have \( x>0, y>0, x<0 \) and \( y<0 \), respectively; therefore, the lattice sums in the regions can be derived in the following manner:

\[
S_n (1) = \frac{1}{(n-1)!} \int_0^\infty \sum_{k=1}^\infty \sum_{j=-k}^k \lambda^{n-1} e^{-\lambda k^2 \omega} d\lambda
\]

(6.7)
The expressions inside the integrals can be analytically summed up. In fact, we have\[\text{[Dienstfrey and Huang, 2001]}\]

\begin{align}
S_n(2) &= \frac{i^n}{(n-1)!} \int_0^\infty \lambda^{n-1} \sum_{j=1}^\infty \sum_{k=j+1}^{j-1} e^{i(\lambda k - j)} \\
S_n(3) &= \frac{(-1)^n}{(n-1)!} \int_0^\infty \lambda^{n-1} \sum_{k=1}^\infty \sum_{j=k}^{k-1} e^{-\lambda (bk + j)} \\
S_n(4) &= \frac{(-i)^n}{(n-1)!} \int_0^\infty \lambda^{n-1} \sum_{j=1}^\infty \sum_{k=j+1}^{j-1} e^{i\lambda (bk - j)}
\end{align}

If the expressions given in (6.7)-(6.10) are summed up, the required lattice sums are obtained. For odd values of \(n\), expressions (6.7)-(6.10) cancel each other out and, as a result, the lattice sums would be zero. For even numbers, the result is

\begin{align}
\tau_1 &= \sum_{k=1}^\infty \sum_{j=k}^{k-1} e^{\lambda (bk + j)} = \frac{e^{ib\lambda} - e^{i\lambda} + e^{ib\lambda + i\lambda} + e^{ib\lambda + 2i\lambda}}{(e^{ib\lambda} - e^{i\lambda})(e^{ib\lambda + i\lambda} - 1)} \\
\tau_2 &= \sum_{j=1}^\infty \sum_{k=j+1}^{j-1} e^{\lambda (bk - j)} = \frac{e^{ib\lambda} (1 + e^{i\lambda})}{(e^{ib\lambda} - e^{i\lambda})(e^{ib\lambda + i\lambda} - 1)}
\end{align}

When calculating the above-mentioned integrals to a sufficient accuracy, the lattice sums can be obtained to a desired accuracy. Note that Eq. (6.13) cannot be used for calculating \(S_2^2\). In fact, this case is conditionally convergent, and completely different values can be obtained for this sum. Rayleigh calculated this sum arbitrarily in the direction of the applied field and his method was questioned because of this. Poulton et al. [1999] have summarized a vast selection of literature pertaining to this subject. Recently, Dienstfrey and Huang [2001] have performed an attempt to include the case \(S_2^2\) in the integral representation.
Similar formulations can be developed for particulate composites. For example, Huang has derived the following integral representation for a simple cubic arrangement of inclusions:

\[
S_{\text{sum}} = C \lambda \int_0^{\infty} e^{-\lambda} \int_0^{2\pi} \left\{ \tau_{\text{ud}} (\lambda, \alpha) \cos (m\alpha) + i^n (\cos \alpha + 1)^m (\sin \alpha)^{n+m} \tau_{\text{new}} (\lambda, \alpha) \right\} / \eta(\lambda, \alpha) \, d\alpha \, d\lambda
\]  

(6.14)

where

\[ C = \frac{1}{\sqrt{(n-m)!}(n+m)!} \]  

(6.15)

\[
\tau_{\text{ud}} = \lambda^3 \left\{ 1 + 2\cos (\lambda \cos \alpha) + 2\cos (\lambda \sin \alpha) + 4\cos (\lambda \cos \alpha) \cos (\lambda \sin \alpha) \\
+ e^{-\lambda} \left[ 1 - 2\cos (\lambda \cos \alpha) - 2\cos (\lambda \sin \alpha) - 4\cos^2 (\lambda \cos \alpha) - 4\cos^2 (\lambda \sin \alpha) \right] \\
+ e^{-2\lambda} \left[ -1 + 4\cos (\lambda \cos \alpha) \cos (\lambda \sin \alpha) \right] - e^{-3\lambda} \right\}
\]  

(6.16)

\[
\tau_{\text{new}} = 2\lambda \left\{ 1 + \cos (\lambda \cos \alpha) + 2e^{-\lambda} \cos (\lambda \cos \alpha) + \cos^2 (\lambda \cos \alpha) \right\} \\
- e^{-2\lambda} \left[ 1 + \cos (\lambda \cos \alpha) + 2\cos (\lambda \sin \alpha) + 2\cos (\lambda \cos \alpha) \cos (\lambda \sin \alpha) \right]
\]  

(6.17)

\[
\eta(\lambda, \alpha) = \left\{ 1 - 2e^{-\lambda} \cos [\lambda (\cos \alpha - \sin \alpha)] + e^{-2\lambda} \left[ 1 - 2e^{-\lambda} \cos [\lambda (\cos \alpha + \sin \alpha)] + e^{-2\lambda} \right] \right\}
\]  

(6.18)

Note that for a simple cubic arrangement, non-zero cases happen when \( n \) is an even number and \( m \) a multiple of 4. Also, as explained, the above relation cannot be used for the case \( n=2 \).

6.2 Calculating lattice sums over reciprocal arrays

Consider the same rectangular array as studied in section (6.1). To calculate the propagation of electromagnetic waves through this medium, the following equation, which is well known as the Helmholtz equation, needs to be solved:

\[
(\nabla^2 + \kappa^2) \mathcal{R}(r) = 0,
\]  

(6.19)

where \( \kappa \) is the wave number, \( r \) the position vector and \( \mathcal{R} \) can be an electric or magnetic field.
Such an investigation can be successfully performed using the Rayleigh method as outlined by many researchers [Poulton et al., 1999]. The final equation, similarly to the discussion in chapter 2, is, again, a linear algebraic system; however, it contains sums of the form

\[ S_d^{\nu}(\kappa) = \sum_j J_\nu^2(\kappa r_j) e^{i\theta_j} \]

over the cylinders, where \( J_\nu^2 \) is the Bessel function of the second kind and order \( n \). Since these lattice sums are frequency–dependent, they are here called them dynamic lattice sums. To obtain an absolutely convergent series and also accelerate the convergence, Chin et al. [1994] have proposed a method to calculate these lattice sums in terms of Bessel functions over the reciprocal array. The reciprocal array is a set of imaginary points constructed for the lattice under study by

\[ r_h = (r_h, \theta_h) = h_1 2\pi i / b + h_2 2\pi j \quad h = (h_1, h_2) \in \mathbb{Z}^2 \]  

(6.20)

The methodology involves a considerable mathematical effort which relies on finding Green’s function of Eq. (6.19) in the direct lattice and in the reciprocal array. Green’s function is the solution of Eq. (6.19) when there is a Dirac function on the right–hand side. It can be shown that Green’s function in the direct array involves dynamic lattice sums, and in the reciprocal array it consists of a convergent summation in terms of Bessel functions. Furthermore, Green’s function in the direct lattice and the reciprocal array are related to each other [Chin et al., 1994; Nicorovici et al. 1995]; thus, relating these two functions, the dynamic lattice sums can be obtained in an absolutely convergent series over a reciprocal array. The final result for the rectangular array is as follows:

\[ S_d^{\nu}(\kappa) J_{2\nu + q}^{\nu}(\kappa) = -\frac{4}{b} (-1)^n \sum_h \left( \frac{\kappa}{r_h} \right)^q J_{2\nu + q}^1 (\kappa r_h) \frac{1}{r_h^2 - \kappa^2} e^{-i2n\theta_h}, \quad n \geq 1 \]  

(6.21)

where \( q > 0 \) is an arbitrary integer parameter. By increasing the value of \( q \), the lattice sums converge more rapidly, but excessively large values of \( q \) may lead to instability in the numerical algorithm. At the long-wavelength limit \( (\kappa \to 0) \), Eq. (6.19) will be reduced to the Laplace equation. In this limit, the lattice sums would be static, i.e. those that are the interest of this thesis. A simplification of (6.21) for this limit [Movchan, 1997] gives
\[ S_{2n} = (-1)^n \pi \frac{(2n + q)^n}{b(2n - 1)^n} \left[ \sum_{k=0}^{1} J_{2n+q}^1 \left( \frac{r_h}{2} \right) e^{-2 \theta_0 \theta_n} + \frac{1}{(q + 2)^n} e^{-2i(\theta_0 + \pi/2) \delta_{n1}} \right], \] (6.22)

where \( \theta_0 \) is the direction of the incident field. All the required lattice sums for the rectangular array can be calculated in this way.

Equally well, the same methodology can be developed for particulate composites. The reciprocal array for a lattice with periodicity equal to \( b, c \) and a unity in the \( x-, y- \) and \( z- \) directions takes the following form:

\[ r_h = (r_h, \theta_h, \phi_h) = h_1 2\pi i/b + h_2 2\pi j/c + h_3 2\pi k, \quad h = (h_1, h_2, h_3) \in \mathbb{Z}^3 \] (6.23)

Nicorovici et al. [1995] have shown that the static lattice sums for this system can be derived from the following formula:

\[ S_{nm} = \frac{(2n + q + 1)^n}{(2n - 1)^n} \frac{4\pi}{bc} \sum_{k=0}^{1} \frac{J_{n+q}^1 \left( \frac{r_h}{2} \right) Y^*_{nm}(\theta_0, \phi_0)}{r_h^{q+2}} + \frac{1}{(q + 5)^n} Y^*_{nm}(\theta_0, \phi_0) \delta_{n2}, \quad n \geq 2, \quad m \geq 0 \] (6.24)

where the asterisk stands for a complex conjugation and \( \theta_0 \) and \( \phi_0 \) are the directions of the applied field.

### 6.3 Results

Table (6.1) shows a sample of the results of the present study for the three-phase fiber composites, which has been obtained using the above methodologies. Although the integral representation requires more computer programming, it is faster than the second method; therefore, all the cases except \( n = 1 \) have been calculated using this method. For cylinders of type two, applying the integral representation technique yields the following:
\[ S^2_{2n} = \frac{1}{\nu^{2n}} + \frac{1}{(2n-1)!} \int_0^\infty \left( e^{\lambda \nu} + e^{-\lambda \nu} \right) \tau_1 + i^{2n} \left( e^{\lambda \nu} + e^{-\lambda \nu} \right) \tau_2 \, d\lambda, \quad \text{(6.25)} \]

where \( \nu = b/2 + i/2 \). For calculating integrals (6.13) and (6.25), well-established methods such as Gauss-Laguerre integration, can be used for this purpose [Press et al., 1986].

Table 6.1 The calculated lattice sums for the case of a three-phase composite of a periodic array of cylinders when \( b = \sqrt{3} \).

In this thesis, these integrals have been calculated using the Mathematica 3 software application, which offers the possibility to check the accuracy of the results. For the case \( S^1_2 \), Eq. (6.22) has been used. \( q \) was selected to be 12, and the computation was performed over a 200\times200\ reciprocal array. Calculating \( S^1_2 \), \( S^2_2 \) can be found simply by using \( S^2_2 = 2\pi/\sqrt{3} - S^1_2 \). Note that for \( n \gg 1 \), the direct summation method can quickly yield accurate results.
7. RESISTOR MODELS FOR DERIVING THE BOUNDS FOR THE EFFECTIVE CONDUCTIVITY

From one perspective, two main approaches for calculating the effective transport properties of composite materials can be identified. According to the first strategy, the efforts are concentrated on directly solving the governing equations of the system [Rayleigh, 1892; Cheng and Torquato, 1997; Lu, 1994]. The second method differs from the first one in that there the aim is to develop bounds (upper-lower) for the effective transport properties of the system [Hashin and Shtrikman, 1962; Torquato et al., 1986; Helsing, 1993]. In general, fewer details of the system are required for the second method; however, using more specifications, tighter bounds may be derived. The best-known bounds are those proposed by Hashin and Shtrikman. Hashin and Shtrikman have shown that the bounds they obtained can be realised for some particular microstructures. The upper bounds can be attained using an assemblage of coated spheres in which the core is filled with a material of higher conductivity; the upper bound is attained using the same structure that changes the material of the core and shell. Since these structures introduce more disconnected-connected microstructures of the phases, Hashin-Shtrikman bounds can be considered to be optimal.

In this section, two simple resistor models are used (see Moosavi et al. [2002b]) for obtaining the bounds on the effective conductivity of systems consisting of simple cubic arrays of multi-coated spheres (or square arrays of cylinders). Figures 7.1 and 7.2 outline the methods for finding two bounds for the effective conductivity of a system. For the lower bound, the methodology given in Fig. 7.1 is used. In this method, the unit cell is divided into infinite layers in the direction of the heat flow. The effective conductivity can be derived as

\[
k_c^+ = \sum_{j=1}^{N+1} a_j^2 - a_{j-1}^2 \int_{\pi/2}^{\pi} \frac{\sin 2\theta d\theta}{\sum_{j=1}^{N+1} 2a_j \sqrt{1 - (a_j \sin \theta / a_j)}^2 (1/k_j - 1/k_{j+1}) + 1},
\]

where

\[
A_j = \frac{a_j^2}{a_j^2 - a_{j-1}^2} \int_{\pi/2}^{\pi} \frac{\sin 2\theta d\theta}{\sum_{j=1}^{N+1} 2a_j \sqrt{1 - (a_j \sin \theta / a_j)}^2 (1/k_j - 1/k_{j+1}) + 1}.
\]
Figure 7.1 Quarter unit cell considered in the derivation of the effective conductivity by using the first resistor model.

For deriving the upper bound, the strategy outlined in Fig. 7.2 is used. In this method, the unit cell is divided into infinite slices normal to the direction of the heat flow. The effective conductivity of the system can be given by

Figure 7.2 Quarter unit cell under inspection in the second resistor model.
\[ k_{e}^{-} = \sum_{i=1}^{N-1} \frac{1}{2(a_i - a_{i-1}) B_i} + 1 - 2a_{N-1}, \]  

(7.3)

where

\[ B_i = \frac{1 - a_{i-1}/a_i}{\sin \theta d \theta} \int_{0}^{\theta_i} \pi k_i (a, \sin \theta)^2 + \sum_{j=i+1}^{N-1} k_j (a_j^2 - a_{j-1}^2) - [a_{N-1}^2 - (a, \cos \theta)^2] \] + 1.

(7.4)

Following the same strategy as discussed above for spheres, it can be shown for the case of a square array of cylinders that

\[ k_{e}^{-} = \sum_{i=1}^{N-1} 2[a_i - a_{i-1}] A_i + 1 - 2a_{N-1}, \]  

(7.5)

where

\[ A_i = \frac{a_i}{a_i - a_{i-1}} \int_{\alpha_i/2}^{\pi/2} \frac{\cos \theta \ d \theta}{\sum_{j=i}^{N-1} 2a_j \sqrt{1 - (a, \sin \theta / a_j)^2 \left(1/k_j - 1/k_{j+1}\right) + 1}}. \]  

(7.6)

and for the lower bound

\[ k_{e}^{-} = \sum_{i=1}^{N-1} \frac{1}{2(a_i - a_{i-1}) B_i} + 1 - 2a_{N-1} \]  

(7.7)

where

\[ B_i = \frac{1 - a_{i-1}/a_i}{\sin \theta d \theta} \int_{0}^{\theta_i} 2\left[k_i a_i \sin \theta + \sum_{j=i+1}^{N-1} k_j \left[\sqrt{a_j^2 - (a, \cos \theta)^2} - \sqrt{a_{j-1}^2 - (a, \cos \theta)^2} \right] - \sqrt{a_{N-1}^2 - (a, \cos \theta)^2}\right] \] + 1

(7.8)
Figure 7.3 shows a typical comparison between the results of the bounds and exact results. The total volume fraction \( F \) was selected to be 0.2 \((f_1 = 0.1 \text{ and } f_2 = 0.1)\). It is perhaps interesting that in some cases the second resistor model yields better results. This is contrary to the natural thinking that since the case is coated and heat goes from one layer to another, considering the resistor in the series should yield better results. Also, it can be seen that the upper bound does not conform to the behaviour of the exact solution when the coating layer is perfectly conducting. The same can be observed when the coating layer is perfectly insulating.

**Figure 7.3** Logarithmic plot of the effective conductivity for the simple cubic array of coating spheres as a function of conductivity of the core and shell. Despite of the accuracy, the first resistor model is unable to show the same behaviour as the exact solution when the shell is perfectly conducting. The same condition applies for the second resistor model when the shell is perfectly insulating.
8. Conclusion

This thesis studied the effective transport properties of multiphase composite materials made up of periodic arrays of circular cylinders, elliptical cylinders and spheres using a methodology indebted to Rayleigh [1892]. For each section, a series of explicit relations for easy calculating of the effective property were reported.

Composites containing inclusions in the shape of coated circular cylinders were considered, the behaviour of singly coated systems, when the sum of the transport property of the layers is zero, was extended to multicoated ones, and a generalisation of this phenomenon was provided. This thesis showed that the procedure for neglecting phases can occur in different methods and that these procedures can affect several layers and also explained the details of these procedures. Furthermore, a formulation for deriving the effective property of composites with a periodic array of confocally multicoated elliptical cylinders was presented and it was shown that, in general, the behaviour observed in composites made up of circular cylindrical inclusions does not hold for these coated composites. However, further study is required to determine whether the coating layers of other shapes (uniform coating, for example) can demonstrate this behaviour. This thesis also explained that contrary to the case of coated circular cylinders, the generalisation behaviour for composites containing singly coated spheres cannot be developed for composites with multicoated spheres. Whenever necessary, the results were verified using classical numerical techniques.

For the case of three-phase composites with inclusions in the shape of circular cylinders, this thesis showed that these materials can exhibit interesting behaviour. By having mono-sized inclusions in a position of contact when the unit cell is a rectangular cylinder and one phase is perfectly conducting and the other insulating, a composite material can be obtained that is super-conducting in one direction and non-conducting in another. If the rectangular array is changed to a square one in the mentioned case, surprisingly, the effect of all the dispersed phases can be neglected.

The effect of interfacial resistance on effective conductivity was studied by characterising interfacial resistance using a non-dimensional parameter. It was shown that this effect is very
important, and on the basis of the value of interfacial resistance, even the effective conductivity of the system can fall outside the range of the property of the phases. The number of situations in which the effect of both phases can be neglected is infinite; however, these situations are usually valid for one direction only. There is only one state that is common and if it occurs, the effect of the inclusions can be neglected despite the direction in which the effective property is calculated. This situation occurs when both phases have an interfacial resistance equal to their conductivity minus one. It was further demonstrated that there is an interfacial resistance, which can be estimated by $R_i \leq k_i - 1$, in which the effect of the inclusions of type $i$ for one direction can be neglected. These results can be applied for the cases of inclusions in the shape of circular cylinders or spheres.

Two resistor models were used for deriving the bounds. The results of the bounds were compared for coated composites, and it was shown that having the resistor in a series does not guarantee that better results will be obtained in all cases. By combining these bounds in a specific manner, better results may be obtained than by using one of them alone. For instance, when an inclusion has a property close to that of the matrix, it is advisable to use a simple average value.

Although the formulation and results of this thesis on multi-phase composite materials have been verified in some cases by relevant theorems and numerical results, comparing them with experimental results can be a crucial task. Unfortunately, the experimental results found in subjects relevant to the study belong mostly to two-phase systems and, in some cases, to three-phase ones. These results have been used by many authors to validate the theoretical formulations and results [Meredith and Tobias, 1960; McPhedran and McKenzie, 1978; Perrins et al., 1979; Nicorovici et al., 1995; Yardley et al., 1999]. Since the formulations and results given in this thesis are in complete agreement with those of the mentioned authors, they have, therefore, already been compared to the experimental results in two- and three-phase systems. However, for the new formulations and results obtained on multi-phase systems in this thesis, the validation of the results with experimental results can be helpful and is suggested as a topic for further study in this field.

We study the resonant behavior of a system consisting of a square array of multi-coated cylinders by calculating the effective dielectric constant of the system. The results were examined numerically using the finite element method.

Keywords: Dielectric constant; resonance; cylinder; multi-coated; finite element method.

1. Introduction

Finding the response of a system consisting of a periodic array of solid cylinders embedded in a homogeneous matrix has a long history dating back to Lord Rayleigh.\(^1\) Runge\(^2\) extended Rayleigh’s method to coated elements where the geometry was composed of an array of tubes and the core of the tubes was filled with the same material as the matrix. Israelachvili et al.\(^3\) reported the solution of the problem when the materials of core and matrix were different.

The inspection of the behavior of the solution as a function of the property of the core and shell divulged a new feature of the system. Nicorovici et al.\(^4-6\) discovered that the procedure of coating the cylinders with a material that has a dielectric constant, which is the negative of that of the cylinders (\(\varepsilon_{\text{shell}} = -\varepsilon_{\text{core}}\)) or matrix (\(\varepsilon_{\text{shell}} = -\varepsilon_{\text{matrix}}\)) can yield the response of a system with magnified cylinders. This means that a system with diminished concentration may conditionally give the response of a concentrated system. These authors termed the system in these situations “partially-resonant” and the conditions that put the system in these particular states the “partial resonances” of the system. The term “resonance” may be misleading here. In fact, the above-mentioned features are a generalization of what happens in two-phase composites when \(\varepsilon_{\text{core}} = -\varepsilon_{\text{matrix}}\), which is not a resonance.\(^7,8\) Therefore, one needs to consider that the term “partial resonance”

*Corresponding author.
only refers to a specific condition. The term "partial" was applied due to the fact that the response of the system in these situations is still limited.

In this report, we elucidate how the above-described behavior occurs in a system consisting of arrays of multi-coated cylinders. The motivation for this research stems from the further need to inspect the behavior of systems with components, which have a negative permittivity (ε) or negative permeability (μ) or systems having both ε and μ negative (the so-called left-handed medium). These systems have shown interesting and unexpected results, which may also be of practical interest.

Note that, although periodic arrays are idealized microstructures they may be realizable experimentally. One reason for studying these structures is that their properties can many times be easily computed. Also, the results of periodic systems can be useful for grasping the interplay between the microstructure and macroscopic properties of composites. We numerically show that a disordered structure can also be partially resonant.

The structure of this report is explained here. The following section describes the geometry under study. In Sec. 3, we briefly explain the procedure of deriving the response of the system. Section 4 predicts some results from the theoretical study of the system when it is in resonant states. Section 5 verifies the results of the previous section and finally, in Sec. 6, we summarize the key findings of this study.

2. Geometric Description

Consider a homogeneous matrix with a unit dielectric constant surrounding an array of composite cylinders, which have a topology based upon the well-known square lattice. Each lattice point of the square array can be described by a lattice vector, \( \mathbf{r}_n \), defined as:

\[
\mathbf{r}_n = h(n_1 \mathbf{e}_{x_1} + n_2 \mathbf{e}_{x_2}),
\]

where \( h \) is the characteristic length that expresses all the dimensionless distances \( n_1 \) and \( n_2 \) are arbitrary integers and the two basic vectors, \( \mathbf{e}_{x_1} \) and \( \mathbf{e}_{x_2} \), form the orthonormal basis of the plane. Let \( \theta \) be an angle measured from the \( x_1 \)-axis. Thus, one can write

\[
x_1 = r \cos \theta, \quad x_2 = r \sin \theta.
\]

The radiiuses of the core and coating layers are determined by \( a_1, \ldots, a_{N-1} \), respectively, as is shown Fig. 1. With these considerations, one can show that the volume fractions occupied by the core and coating layers can be obtained from

\[
f_i = \pi(a_i^2 - a_{i-1}^2) \quad (i = 1, \ldots, N - 1)
\]

and the total volume fraction can be expressed as:

\[
F = \sum_{i=1}^{N-1} f_i.
\]
The resonant behavior of a multi-phase composite material has been included here and in the following relations in order to reduce the number of mathematical notations. We also use the term "layer" for the core, coating layers and matrix, and the dielectric constant ratio between layers $i-1$ and $i$ is represented by $\varepsilon_{i-1,i}$.

3. Mathematical Modeling

Considering the problem symmetrical allows it to be solved independent of the direction of the applied field and without compromising generality, we assume a potential gradient of unit magnitude to be applied along the $x_1$-axis. For the unit cell located at the origin, considering the general solution of the Laplace equation in polar coordinates $(r, \theta)$ and following Ref. 1, the potential $(V)$ inside the layers may be given as:

$$
V^1 = \sum_{n=1}^{\infty} E_n^1 r^{2n-1} \cos(2n-1)\theta \quad r \leq a_1, 
$$

(5a)

$$
V^i = \sum_{n=1}^{\infty} \left[ E_n^i r^{2n-1} + F_n^i r^{-2n+1} \right] \cos(2n-1)\theta \quad a_{i-1} \leq r \leq a_i (i = 2, \ldots, N - 1),
$$

(5b)

$$
V^N = \sum_{n=1}^{\infty} \left[ E_n^N r^{2n-1} + F_n^N r^{-2n+1} \right] \cos(2n-1)\theta \quad r \geq a_{n-1},
$$

(5c)

where $E^i_n$ and $F^i_n$ are unknown coefficients that are to be determined.
At all the surfaces between the layers, the potential and normal component of the electric displacement are continuous, i.e.,

\[
\begin{align*}
V^1 &= V^2 \\
\varepsilon_1 \frac{\partial V^1}{\partial r} &= \varepsilon_2 \frac{\partial V^2}{\partial r} \\
\varepsilon_{i-1} \frac{\partial V^{i-1}}{\partial r} - \varepsilon_i \frac{\partial V^i}{\partial r} &= r = a_{i-1}(i = 2, \ldots, N - 1) , \\
\varepsilon_{N-1} \frac{\partial V^{N-1}}{\partial r} - \varepsilon_N \frac{\partial V^N}{\partial r} &= r = a_{N-1} .
\end{align*}
\]

By applying Eqs. (6) \(E_n^i\) and \(F_n^i\) can be related to each other as:

\[
F_n^i + \ell_n^i a_{i-1}^{4n-2} E_n^i = 0 \quad (i \geq 2)
\]

where

\[
\ell_n^i = \frac{\varepsilon_{i-1,i} - 1 + (\varepsilon_{i-1,i} + 1)L_i^{i-1}(a_{i-2}/a_{i-1})^{4n-2}}{\varepsilon_{i-1,i} + 1 + (\varepsilon_{i-1,i} - 1)L_i^{i-1}(a_{i-2}/a_{i-1})^{4n-2}} .
\]

To derive \(E_n^N\) and \(F_n^N\), one may follow the method of Zuzovski and Brenner.\(^{13}\) These authors derived another relation for the potential through the matrix in one unknown \(A_n\). Comparing the resultant relation with Eq. (5c), allows two linear equations to be found relating \(E_n^N\) and \(F_n^N\) to \(A_n\). These two equations yield a set of linear equations in the unknowns \(A_n\) with the help of Eq. (7)

\[
\frac{A_n}{a_{N-1}^{4n-2} F_n^N} = - \sum_{J=1}^{\infty} \left( \frac{2n + 2J - 1}{2n + 1} \right) S_{2n+2J,A,4n-2} + \delta_{n0} ,
\]

where \(\delta_{n0}\) represents the Kronecker delta (1 for \(n = 0\) otherwise 0) and \(S_n\) are constants characteristic of the array. After finding \(E_n^N\) and \(F_n^N\), other coefficients can be found by using Eqs. (6).

The effective dielectric constant can be calculated using the following formula

\[
\varepsilon_{eff} = 1 + 2\pi A_0 ,
\]

where \(A_0\) can be derived by solving the system of linear algebraic equations obtained from Eq. (9). As a solution in an explicit form, we present the following simple formula, which gives reasonable results in very low volume fractions

\[
\varepsilon_{eff} = 1 - \frac{2F}{-1/L_i^N + F} .
\]

In order to obtain a more accurate expression one can use the methods outlined by Manteufel and Todreas.\(^{14}\)
4. Theoretical Prediction

As can be seen from Eq. (9), \( a_{N-1} \) and \( L_N^N \) play important roles in the response of the system to the applied field. Due to the form of the mathematical expression of \( L_N^N \) [i.e., Eq. (8)], for some cases, there may exist a different number and series of dispersed layers that provide following relation

\[
a_{N-1}^{4n+2} L_{N+1}^N = a_{N-1}^{4n+2} L_{N+1}^N
\]

and, as a result, the response of the system in these situations would be the same. For example, when the coating layer \( i \) is perfectly conducting or insulating, \( L_i^{i+1} \) would be \( 1 \) and \( -1 \), respectively. This means that the layers under the layer \( i \) will have no effect on the calculation of \( L_N^N \). Thus, there are infinite selections for the number and property of the layers under the layer \( i \).

The particular cases occur when

\[
\varepsilon_{i-1} + \varepsilon_i = 0 \quad (2 \leq i \leq N). \tag{13}
\]

From Eq. (8) we find the following

\[
L_i^{i+1} = \frac{P + Q}{R + S} \quad (1 \leq i \leq N - 1) \tag{14}
\]

where

\[
\begin{align*}
P &= (\varepsilon_{i,i+1} - 1) \left[ \varepsilon_{i-1,i} + 1 + (\varepsilon_{i-1,i} - 1)L_{i-1}^{i-1} \left( \frac{a_{i-2}}{a_{i-1}} \right)^{4n-2} \right] \\
Q &= (\varepsilon_{i,i+1} + 1) \left[ \varepsilon_{i+1,i} - 1 + (\varepsilon_{i+1,i} + 1)L_{i-1}^{i-1} \left( \frac{a_{i-2}}{a_{i-1}} \right)^{4n-2} \right] \\
R &= (\varepsilon_{i,i+1} + 1) \left[ \varepsilon_{i-1,i} + 1 + (\varepsilon_{i-1,i} - 1)L_{i-1}^{i-1} \left( \frac{a_{i-2}}{a_{i-1}} \right)^{4n-2} \right] \\
S &= (\varepsilon_{i,i+1} - 1) \left[ \varepsilon_{i-1,i} + 1 + (\varepsilon_{i-1,i} - 1)L_{i-1}^{i-1} \left( \frac{a_{i-2}}{a_{i-1}} \right)^{4n-2} \right]
\end{align*}
\]

Substituting condition (13) into Eq. (14) gives the following statement

\[
I_i^{i+1} = \frac{\varepsilon_{i-1,i+1} - 1 + (\varepsilon_{i-1,i+1} + 1)L_{i-1}^{i-1}(a_{i-2}/a_i)^{4n-2}(a_i/a_{i-1})^{2(4n-2)}}{\varepsilon_{i-1,i+1} + 1 + (\varepsilon_{i-1,i+1} - 1)L_{i-1}^{i-1}(a_{i-2}/a_i)^{4n-2}(a_i/a_{i-1})^{2(4n-2)}}. \tag{15}
\]

If two layers, \( i - 1 \) and \( i \), have the same dielectric constant, which is equal to \( \varepsilon_{i-1} \), one may derive the following

\[
I_i^{i+1} = \frac{\varepsilon_{i-1,i+1} + 1 + (\varepsilon_{i-1,i+1} + 1)L_{i-1}^{i-1}(a_{i-2}/a_i)^{4n-2}}{\varepsilon_{i-1,i+1} + 1 + (\varepsilon_{i-1,i+1} - 1)L_{i-1}^{i-1}(a_{i-2}/a_i)^{4n-2}}. \tag{16}
\]

A comparison of Eqs. (16) and (17) shows that the field through the continuous phase would be the same if layer \( i \) had the same property as layer \( i - 1 \) and all
the layers under layer \( i - 1 \) were magnified by a factor of \( (a_i/a_{i-1})^4 \). Layer \( i - 1 \) experiences two changes. Magnification by occupying the place of layer \( i \) and reduction due to the extension of layer \( i - 2 \). Thus, this case can be materialized only if

\[
a_{i-1} > \sqrt{a_i a_{i-2}}. \tag{18}
\]

The inspection of \( L_n^{i+1} \) in condition (13) revealed part of the results. Let us now derive an expression for \( L_n^i \). From Eq. (8) after substituting Eq. (13) and developing a relation for \( L_n^{i-1} \) analogous to Eq. (8), the following equation can be derived

\[
L_n^i = \frac{\varepsilon_{i-2,i} - 1 + (\varepsilon_{i-2,i} + 1)L_n^{i-2}(a_{i-3}/a_{i-1})^{4n-2}(a_{i-1}/a_{i-2})^2}{\varepsilon_{i-2,i} + 1 + (\varepsilon_{i-2,i} - 1)L_n^{i-2}(a_{i-3}/a_{i-1})^{4n-2}(a_{i-1}/a_{i-2})^2} \times \left(\frac{a_{i-1}}{a_{i-2}}\right)^{4n-2} (2 \leq i \leq N). \tag{19}
\]

When two layers, \( i - 1 \) and \( i - 2 \), have the same dielectric constant equal to \( \varepsilon_{i-2} \), the result for \( L_n^i \) would be

\[
L_n^i = \frac{\varepsilon_{i-2,i} - 1 + (\varepsilon_{i-2,i} + 1)L_n^{i-2}(a_{i-3}/a_{i-1})^{4n-2}}{\varepsilon_{i-2,i} + 1 + (\varepsilon_{i-2,i} - 1)L_n^{i-2}(a_{i-3}/a_{i-1})^{4n-2}}. \tag{20}
\]

A comparing of Eqs. (19) and (20) indicates that there is another equivalent system in which all the layers (\( i = 1, \ldots, i - 3 \)) have been extended by a factor of \( (a_{i-1}/a_{i-2})^4 \). The layer \( i - 1 \) now has the property equal to that of layer \( i - 2 \) and its outer radius is \( a_{i-1} \times (a_{i-1}/a_{i-2}) \). This system can be materialized if

\[
a_{i-1} < \sqrt{a_i a_{i-2}}. \tag{21}
\]

Some conclusions can be drawn on the basis of the above relations. When \( i - 2 \) in Eq. (13), the second equivalent system cannot occur, but there is always an equivalent system. When \( 3 \leq i \leq N - 1 \), both equivalent systems can occur, although not simultaneously because of the limitations dictated in Eqs. (18) and (21), which contravene each other. Therefore, finding the equivalent system in this situation has been warranted except when \( a_{i-1} = \sqrt{a_i a_{i-2}} \). If \( i = N \), the first equivalent system has no meaning and the second one can occur if \( a_{i-1} < \sqrt{a_i - 2}/2 \).

Since Eq. (13) expresses resonance between two successive layers, one may consider different cases in which several pair layers satisfy relation (13), i.e.,

\[
\varepsilon_{i-1} + \varepsilon_i = 0 \quad (i = j, k, l, \ldots). \tag{22}
\]

The behavior of the system in these states can be readily detected by successively applying the methods declared above. For example, we consider the following case

\[
\varepsilon_{i-1} + \varepsilon_i = 0 \quad (i = 2, \ldots, N - 1). \tag{23}
\]

Successively employing the methods ultimately indicates that the field inside the matrix would not change if the multi-coated cylinders were replace by solid cylinders.
of radius \( a_{N-1} \) and dielectric constant \( \varepsilon_1 \). Therefore it can be shown that \( L_n^N \) can be simplified into the following form

\[
L_n^N = \frac{\varepsilon_1 - 1}{\varepsilon_1 + 1}
\]

and as a result, the potential inside the matrix would be

\[
V_n^N = \sum_{n=1}^{N} F_n^N \left[ \frac{1 + \varepsilon_1}{(1 - \varepsilon_1) a_{N-1}^{4n^2-2}} r^{2n-1} + r^{-2n+1} \right] \cos(2n-1)\theta.
\]

From the above result, it can be understood that in this situation, the sign of \( \varepsilon \) for the layers between layers 1 and \( N (1 < i < N) \) can be arbitrarily chosen and all the cases yield the same response.

When all the layers \( (i = 2, \ldots, N) \) fulfill condition (13) and \( N \) is an odd number, the system behaves like a solid medium with the dielectric constant of the matrix.

5. Numerical Verification

Numerical simulation is nowadays a well-developed tool for inspecting the response of systems. Although the unit cell of the periodic structures has been largely simulated,\(^{15}\) they are mostly in two-phase with positive transport properties.

For given geometry and solid volume fractions, the Matlab PDE toolbox was utilized and the Laplace equation solved for a unit cell of the system using the finite element method. The unit cell consists of matrix and dispersed layers (core and coating layers). A potential gradient of unit magnitude was applied externally along the \( x_1 \)-axis and other external boundaries were insulated. At the surfaces between the layers, continuity conditions (6) were implemented. By using solution-adaptive refinement, one can add cells where they are needed in the mesh, thus enabling the features of the potential field to be better resolved. Based on the theoretical findings, the three considerable cases were studied numerically.

- Figure 2(a) shows a unit cell of a system consisting of three-coated cylinders. The dielectric constants of the core and coating layers were selected to be +2.5, +5, +2 and −2 and the radiiuses 0.15, 0.2, 0.275 and 0.33, respectively. In order to construct the equivalent system [Fig. 2(b)], second and third coating layers were joined together and considered as one unit layer with a dielectric constant equal to +2. Also, the core and first coating layers are magnified by the factor \((0.33/0.275)^4\). Therefore, the radiiuses of the layers are \( a_1^* = 0.216, a_2^* = 0.288 \) and \( a_3^* = 0.33 \). The distributions of the induced fields are given in the figures show that although the fields inside the dispersed layers of the systems are completely different, they are exactly the same through the matrix.

- Now we consider the system of Fig. 2(a) with one alteration. In order to satisfy condition (21), the radius of the third coating layer has been extended to the value 0.4 as is shown in Fig. 3(a). Based on the predicted scheme for the second equivalent system, we assemble a two-coated cylinder [Fig. 3(b)] with radiuses
Fig 2. Equipotential contours inside the unit cell of the first case. The original system (a) and equivalent system (b).
Fig. 3. Equipotential contours inside the unit cell of the second case. The original system (a) and equivalent system (b).
Fig. 4. Induced potential field inside the layers of the unit cell in third case. The original (a) and equivalent system (b).
Fig. 5. Induced potential fields inside the layers of a simple system composed of a two-coated cylinder and arbitrary boundaries. The original (a) and equivalent system (b). Note that the potential fields outside the first coating layers are equal. This is also correct for the third case.
of \( a_1^2 = 0.28359375 \), \( a_2^2 = 0.378125 \), and \( a_3^2 = 0.4 \). The dielectric constants of the layers are +2.5 for the core, +5 for the first coating layer and -2 for the second coating layer. It is clear from the figures that the potential fields outside \( a_2^2 \) are equal.

- In third case, a two-coated cylinder has been considered as depicted in Fig. 4(a). The dielectric constants of the core and coating layers are -2, +2 and -2, respectively. In the next system [Fig. 4(b)], the two-coated cylinder is replaced by a solid cylinder with the same dielectric constants as the core of the original system. Both systems have the same total volume fraction. Again, by applying the same boundary conditions, the fields through the matrix of both systems are the same.

To further investigate this subject, we consider a simple system consisting of a two-coated cylinder (with details explained in the third case above) covered by another material of unit dielectric constant. Arbitrary boundary and boundary conditions were selected and implemented on the system as is represented in Fig. 5(a). Figure 5(b) shows that changing the dielectric constant of the first coating layer to -2 causes no disturbance in the field through the matrix. Therefore, disordered structures can also be partially resonant. This fact had been predicted by Nicorovici et al.\(^5\)\(^6\) and the numerical investigation shows the same result.

6. Summary

Inspection of the resonant behavior of the multi-coated structures exposed new results in this field. When the sum of the dielectric constants of two successive layers is equal to zero, a series of layers can be magnified and the magnification is not limited to one layer. The ratio of magnification for the layers detailed. We also explained that, for every resonant state, there may be two types of equivalent system, although only one of them may be of any physical significance. All the numerical investigations were in accordance with the theoretical predictions.

ABSTRACT Two premeditated resistor models have been developed and tested for the prediction of the effective thermal conductivity of a periodic array of multi-coated spheres embedded in a homogeneous matrix of unit conductivity. The results have been compared and evaluated with the exact solution, as obtained by extending a method originally devised by Zuzovski and Brenner. The results for the two models were found to yield bounds for the exact solution. For some situations, the model results match well with the exact solution, but in other cases the results for one of the models could deviate from the exact solution.

1 Introduction

Many studies have been conducted on calculating the effective thermal conductivity of a composite medium consisting of a periodic array of spheres embedded in an isotropic matrix. The basic work for the solid spheres has been outlined by Maxwell [1], who inspected the effective conductivity of a dilute spherical dispersion. Rayleigh [2] described the polarization of each sphere in an external field by an infinite set of multipole moments and gave a relation of low order for a simple array of spheres. His solution was corrected later by Runge [3] and improved by Meredith and Tobias [4]. Maxwell’s theory was extended by Jeffrey [5] to higher particle concentrations. McPhedran et al. [6] modified Rayleigh’s method to overcome a non-absolutely convergent series involved in the solution. Zuzovski and Brenner [7] presented another method that avoids the problems encountered in Rayleigh’s original method. Sangani and Acrivos [8] modified the Zuzovski–Brenner method to circumvent the tedious algebra encountered in the calculations.

Runge [4] developed Rayleigh’s method to coated elements where the geometry was composed of an array of tubes having the same core material as the matrix. Lurie and Cherkaev [9] showed that the bounds on the effective conductivity derived by Hashin and Shtrikman [10] for three-phase composites are realizable for coated sphere assemblages. Yu et al. [11] derived a relation for the effective properties of coated spheres in the dilute limit. Nicorovici et al. [12] extended Rayleigh’s method for a simple cubic array of coated spheres and inspected the behaviour of the solution as a function of the properties of the core and shell of the sphere. Lu and Song [13] and Lu [14] developed a boundary collocation scheme to compute the effective conductivity of a simple array of multi-coated spheres and derived a relation for the effective conductivity of the random array of coated and multi-coated spheres which is correct to $O(F^2)$ where $F$ is the total volume fraction.

In this report, we extend the Zuzovski–Brenner method to multi-coated spheres. We also present a scheme for deriving the effective conductivity of the system using two resistor models and compare the results with the exact solution. It should be noted that the formulation and the results for the thermal conductivity could be applied exactly to the seven other associated transport properties listed by Batchelor [15]. (These properties include electrical conductivity, dielectric permittivity, magnetic permeability, mobility, permeability of a porous medium, modulus of torsion in a cylindrical geometry and effective mass in bubbly flow.)

This paper is organized as follows. The next section describes the geometry under study. Section 3 reports the details of one approach [7] for calculating the effective conductivity of a cubic array of multi-coated spheres embedded in a homogeneous matrix of unit conductivity, and presents the exact solution for this system. Section 4 develops two resistor models for deriving the conductivity of the system. In Sect. 5, the results of the two resistor models are compared and evaluated with the exact solution. Finally, Sect. 6 summarizes the key findings of the study.

2 Geometric description

Consider a homogenous matrix with unit conductivity surrounding an array of composite spheres with a topology based upon the well-known cubic lattices, i.e. the simple cubic (SC) lattice, the body-centered cubic (BCC) lattice and the face-centered cubic (FCC) lattice. Each lattice point of a cubic array can be described by a lattice vector $r_n$ defined as:

$$r_n = h (n_1 a_1 + n_2 a_2 + n_3 a_3)$$

(1)
where \( h \) is the characteristic length to express all the distances in dimensionless form and \( n_1, n_2, \text{and } n_3 \) are arbitrary integers. The three basic vectors \( a_1, a_2 \text{ and } a_3 \) belonging to a SC, BCC and FCC lattice are given in Table 1.

The radius of the core is determined by \( a_1 \) and the other coating layers of the multi-coated sphere are \( a_2, \ldots, a_{N-1} \) respectively, as shown in Fig. 1. The conductivity ratio between the inner and outer layers may be given by:

\[
T^N = x_1 + GH
\]

where \( G \) is the differential operator, whose preferred form for a cubic array of spheres later was derived by Sangani and Acivos [8] as:

\[
G = \sum_{M=0}^{\infty} \sum_{m=0}^{M} \frac{2^{4m-1}}{(2n+1)!} A_{nm} \frac{\partial^{2n+1}}{\partial x_1^{2n+1}}
\]

\[
\times \left\{ \left( \frac{\partial}{\partial \xi} \right)^{4m} + \left( \frac{\partial}{\partial \eta} \right)^{4m} \right\} (M = n + 2m)
\]

where

\[
\xi = x_2 + ix_3, \quad \eta = x_2 - ix_3
\]

and

\[
H = \frac{1}{r} - \sigma + \frac{2\pi}{3} r^2
\]

\[
+ \sum_{n=2}^{\infty} \sum_{m=0}^{\infty} \epsilon_m \left( \frac{2n-4m}{(2n+4m)!} S_{nm} r^{2n} P_{2n}^m \cos \theta \right) \cos m\varphi
\]

where \( \epsilon_m \) represents the Neumann symbol (1 for \( m = 0 \) and 2 otherwise). The calculated values of constant array \( \sigma \) for the three cubic arrays [16] are 2.837297, 3.639233 and 4.584862 for SC, BCC and FCC respectively. The lattice sums have the following form:

\[
S_{lm} = \sum_{n=1}^{\infty} |r_n|^{-2(l+1)} P_{2l}^m \cos \varphi_n \cos m\varphi
\]

TABLE 1 The basic vectors \( a_1, a_2 \) and \( a_3 \) for three cubic lattices. The vectors \( e_x, e_y \) and \( e_z \) form an orthonormal basis in space

The three basic vectors \( a_1, a_2 \) and \( a_3 \) belonging to a SC, BCC and FCC lattice are given in Table 1.

3 The exact solution

The symmetry of the geometry makes the solution of the problem independent of the applied external gradient temperature, which is assumed to occur along the \( x_1 \)-axis. Since the arrays are periodic, we just study a unit cell of the systems. For the unit cell located at the origin, considering the general solution of the Laplace equation in spherical coordinates \( (r, \theta, \varphi) \) and following Rayleigh [2], the temperature inside the layers may be given by:

\[
T^1 = \sum_{n=1}^{\infty} \sum_{m=0}^{\frac{n-1}{2}} E_{nm} r^{2n-1} P_{2n-1}^m (\cos \theta) \cos m\varphi
\]

\[
T^i = \sum_{n=1}^{\infty} \sum_{m=0}^{\frac{n-1}{2}} \left[ E_{n1} r^{2n-1} + F_{nm} r^{2n-2} \right] P_{2n-1}^m (\cos \theta) \cos m\varphi
\]

\[
(i = 2, \ldots, N)
\]

where \( P_M^L(\cos \theta) \) represents the associated Legendre polynomial of degree \( L \) and order \( M \). Zuzovski and Brenner [7] proposed another suitable expression for the temperature inside the continuous phase:
where their values may be calculated by direct summation or in some region of \(l \) and \(m\) by approximate correlation [6, 17]. Note that \(\theta_c\) and \(\varphi_c\) are polar and azimuthal angles measured from the lattice point \(n\).

The unknown coefficients \(A\) in (8) can be determined by implementing boundary conditions at the surface of the core and coating layers:

\[
T^{i-1} = T^i, \quad (k_{i-1}) \partial T^{i-1} / \partial n = \partial T^i / \partial n \quad r = a_{i-1}.
\]

Using these conditions, the following result is obtained:

\[
F_{nm}^i + \lambda^{-1} a_{mi}^{-1} E_{nm}^i = 0 \quad i \geq 2
\]

where

\[
\begin{align*}
L_n^i &= (2n-1) (k_{i-1,j-1} + [2 n (k_{i-1,i} + 1) - 1] (a_{i-2,j-1} a_{i-1,-1}^{n-1}) \\
&\quad \left[ (2n-1) (k_{i-1,j} + 1) + 2 n (k_{i-1,i} - 1) L_n^{i-1} (a_{i-2,j-1} a_{i-1,-1}^{n-1}) \right].
\end{align*}
\]

Calculating \(T^N\) by using the above expressions for \(H\) and \(G\) and comparing the resulting relation with (5), two linear equations can be found relating \(F_{nm}^i\) and \(F_{nm}^i\) to \(A_{nm}\). These two equations combined with (13) yield a set of linear equations in the unknowns \(A_{nm}\):

\[
A_{nm} = \frac{L_n^N}{2(M + 4m + 1)!} \sum_{j=0}^{\infty} \sum_{j=0}^{\infty} \left[ \frac{\lambda_1 \delta_{q1} (2p - 4q_1)!}{(2J - 4j + 1)} S_{p1}^1 + \frac{\lambda_2 \delta_{q1} (2p - 4q_2)!}{(2J - 4j + 1)} S_{p2}^1 \right]
\times A_{j-1,j} + \delta M_{0} L_n^N a_{n-1}^3 \left( 1 + \frac{4\pi}{3\Omega} A_{00} \right)
\]

where

\[
\begin{align*}
p &= M + J + 1, \quad q_1 = m + j, \quad q_2 = |m - j| \\
\lambda_1 &= \lambda_2 = 0.25 \quad \text{if} \quad j \neq 0, m = 0 \\
\lambda_1 &= 0.5, \quad \lambda_2 = 1 \quad \text{if} \quad m = j \neq 0 \\
\lambda_1 &= \lambda_2 = 0.5 \quad \text{otherwise}
\end{align*}
\]

The effective thermal conductivity can be calculated using the following formula:

\[
k_{\text{eff}} = 1 + 4\pi A_{00} / \tau_0
\]

### 3.1 The Explicit Expression

As outlined by Manteufel and Todreas [18] different methods can be used to derive an explicit expression. By using linear truncation, Nicovici et al. [12] have developed a relation of low order for the simple cubic lattice of coated spheres. For the truncation order \(L = 4\), the solution of (15) is given as follows:

\[
k_{\text{eff}} = 1 - \frac{3F}{D}
\]

where

\[
D = -1/L_1^N + F + c_1 L_1^N F^{10/3} 1 + c_2 L_1^N F^{11/3} + c_3 L_1^N F^{14/3}
\]

\[
+ c_4 L_1^N F^{6} + c_5 L_1^N F^{22/3} + O (F^{25/3})
\]

The numerical constants are given in [8] and have been represented here in Table 2. These constants were verified as part of the current work. In (19), if the terms containing \(c_4 - c_6\) are neglected, the formula of truncation order \(L = 3\) can be obtained. By taking \(c_2\) to \(c_6\) equal to zero, the expression of the second-order approximation (\(L = 2\), analogous to that of Lord Rayleigh [2] for the simple cubic lattice of solid spheres, will be obtained:

\[
k_{\text{eff}} = 1 + 3F L_1^N + O (F^2)
\]

Extending (22) for coated spheres gives the following result:

\[
k_{\text{eff}} = 1 + 3L_1^N + 1 + 3F
\times \left( (k_2 - 1) + (1 + 2k_2) [(k_1 - k_2) / (k_1 + 2k_2)] (a_1 / a_2)^3 \right)
\times (k_2 + 2) [(k_1 - k_2) / (k_1 + 2k_2)] (a_1 / a_2)^3.
\]

Likewise, the expression for doubly coated spheres is as follows:

\[
k_{\text{eff}} = 1 + 3L_1^N + 1 + 3F P + Q R + S
\]

where

\[
\begin{align*}
P &= (k_3 - 1) [(k_2 + 2k_3) + (k_2 - k_3)] [(k_1 - k_2)
\quad / (k_1 + 2k_2)] (a_1 / a_2)^3 \\
Q &= (1 + 2k_3) [(k_2 - k_3) (a_2 / a_3)^3 + (k_3 + 2k_2) [(k_1 - k_2)
\quad / (k_1 + 2k_2)] (a_1 / a_2)^3 \\
R &= (k_3 + 2) [(k_2 + 2k_3) + (k_2 - k_3)] [(k_1 - k_2)
\quad / (k_1 + 2k_2)] (a_1 / a_2)^3 \\
S &= 2 (k_3 - 1) [(k_2 - k_3) (a_2 / a_3)^3 + (k_3 + 2k_2) [(k_1 - k_2)
\quad / (k_1 + 2k_2)] (a_1 / a_2)^3.
\end{align*}
\]

TABLE 2 Numerical constants in explicit expression
FIGURE 2  Part of the resistor network. Original (a) and simplified arrangements (b, c)

Setting \( a_3 = 1 \) in (25) will reduce (23) and (24) to the same equations given by Yu et al. [11, 19] for the effective properties of coated and doubly coated spheres in the dilute limit.

3.2  The effect of azimuthal terms for a simple cubic array

The simple cubic array is of interest since it permits spheres to come closer to touching for low-volume-fraction systems as compared to any other arrangement. McPhedran et al. [6] have inspected the effect of azimuthal terms for a simple array of solid spheres. Due to the very small differences between the results, it was not clear whether considering azimuthal terms causes these differences or whether they are just numerical artifacts. This problem was again studied by Sanganli and Acrivos [8], but due to the lack of convergence these authors were not able to obtain reliable results. Table 3 compares the calculated values of effective thermal conductivity for the most sensitive case of perfectly conducting spheres (meaning that the core and all coating layers are perfectly conducting) with the resulting values without azimuthal terms and with those obtained by McPhedran et al. [6]. For this calculation, the effective conductivity without azimuthal terms can be obtained by reducing (14) to the following expression:

\[
\frac{A_{n,0}}{a_{N-1}^{4n+3} A_{n+1}^b} = \sum_{j=1}^{\infty} \left( \frac{2n + 2J}{2n + 1} \right) S_{2n+2j,0} A_{j-1,0} + \delta_{n,0}. \tag{26}
\]

Mathematica 3.0 was used to solve the set of linear algebraic equations obtained from (15) and (26). 50 zonal unknowns and 50 azimuthal unknowns were considered in solving (15) and (26). All elements of the right-hand-side column vector have values of zero except for the first position, which has a value of unity. Multiplying the matrix of coefficients in the column vector of the results and comparing with the right-hand-side vector tests the correctness of the solution. The effective conductivity may be directly calculated from (18). It is clear from the results that there is a real (although small) effect associated with the azimuthal terms.

4  Resistor modeling

The unit cell can be considered to consist of an infinite series of resistors (Fig. 2a). Hsu et al. [20, 21] assumed for two-phase composite materials that all the resistors in the direction normal to the applied heat flow have infinite resistance. Thus they suggested a simplified configuration as shown in Fig. 2b. Another simplified configuration can be considered in which the resistors in the direction normal to the applied heat flow are perfectly conducting resistors, as shown in Fig. 2c. In the discussion that follows, the effective heat conductivity of the system will be derived using both methods, and the accuracy of the results and behaviour of the solutions will be compared with the exact solution. Since similar results could be expected for three cubic arrays, here only the simple cubic array is investigated.

4.1  First resistor model

Suppose that the unit cell is divided to \( N \) parallel regions, each composed of infinite infinitesimal parallel elementary volumes in annular cylinder geometry. Due to the symmetry of the problem and for the sake of simplicity, only a quarter of the unit cell needs to be considered, as depicted in Fig. 3a,b. An expression for the thermal conductivity of each element in these parallel regions (\( \kappa \)) can be

TABLE 3  Effective thermal conductivity for a simple cubic array of perfectly conducting solid spheres. \( \kappa'_{\text{eff}} \) corresponds to the solution without considering azimuthal terms and \( \kappa''_{\text{eff}} \) are results of McPhedran et al. [6]
derived:

\[
\frac{1}{2} \kappa = \sum_{j=i}^{N-1} \frac{a_j \sqrt{1 - (a_i \sin \theta / a_j)^2} - a_{j-1} \sqrt{1 - (a_i \sin \theta / a_{j-1})^2}}{k_j} 
+ \frac{1}{2} - a_{N-1} \sqrt{1 - (a_i \sin \theta / a_{N-1})^2}

= \sum_{j=i}^{N-1} a_j \sqrt{1 - (a_i \sin \theta / a_j)^2} \left( \frac{1}{kJ} - \frac{1}{kJ+1} \right) + \frac{1}{2} 
(i = 1, \ldots, N - 1). 
\]

(27)

Clearly, for the last region, the thermal conductivity is equal to the unit value. The next step is to determine the relation for the equivalent thermal conductivity of each region \(K_i\).

Using (27) and remembering that all elements are in parallel, the following result is obtained:

\[
K_i = \frac{1}{a_i^2 - a_{i-1}^2} \left[ \frac{a_i^2 \sin 2\theta d\theta}{\pi/2} \sum_{j=i}^{N-1} 2a_j \sqrt{1 - (a_i \sin \theta / a_j)^2} (1/k_j - 1/k_{j+1}) + 1 \right] 
(i = 1, \ldots, N - 1) 
\]

(28)

where

\[
\theta_i = \sin^{-1} \left( \frac{a_{i-1}}{a_i} \right), \quad (29)
\]

With the above procedures, the effective conductivity of the unit cell can be derived to be:

\[
k_{\text{eff}} = \sum_{i=1}^{N-1} \pi \left[ a_i^2 - a_{i-1}^2 \right] K_i + 1 - \pi a_N^2 \quad (30)
\]

### 4.2 Second resistor model

As shown in Fig. 4a,b, in the second method the unit cell is divided into infinite slices normal to the applied field. As for the first method, an infinite number of cells in \(N\) serial regions \((i = 1, \ldots, N)\) are considered. For each slice, the equivalent conductivity may be specified as:

\[
\kappa = \sum_{i=1}^{N} K_i s_i / S \quad (i = 1, \ldots, N - 1) 
\]

(31)

where

\[
s_j = \pi \left[ a_j^2 \left[ 1 - (a_i \cos \theta / a_j)^2 \right] \right] 
- a_{j-1}^2 \left[ 1 - (a_i \cos \theta / a_{j-1})^2 \right] \quad \text{if } j = i, \ldots, N - 1
\]

\[
s_j = 1/4 - \pi \left[ a_j^2 - (a_i \cos \theta)^2 \right] \quad \text{if } j = N
\]

(32)

and \(S = 1/4\) is the non-dimensional cross-sectional area of the slice. It is then straightforward to derive the equivalent ther-
mal conductivity of each region as:

\[
K_i = \frac{a_i - a_{i-1}}{\int_0^\pi k_i (a_i \sin \theta)^2 + \sum_{j=i+1}^{N-1} k_i (a_j^2 - a_{j-1}^2) - [a_{N-1}^2 - (a_i \cos \theta)^2] \, d\theta + 1}
\]

\[i = 1, \ldots, N-1\] (33)

where

\[
\theta_i = \cos^{-1}\left(\frac{a_{i-1}}{a_i}\right).
\]

Consequently, the effective conductivity of the system is given as follows:

\[
\kappa_{\text{eff}} = \frac{1}{\sum_{i=1}^{N-1} 2(a_i - a_{i-1})/K_i + 1 - 2a_{N-1}}
\]

(35)

5 Results and discussion

Figure 5 compares the resulting effective thermal conductivity values from the exact solution for the simple array of coated spheres with those obtained from resistor models. The total volume fraction \((F)\) was selected to be 0.2 \((f_1 = 0.1\) and \(f_2 = 0.1\)) and the exact solution was obtained using (19), which should yield reasonable results in this limit [6]. All integrals in (28) and (33) were calculated using the Gauss–Legendre integration technique [22]. The results show that the first method always underestimates the exact solution except when the conductivity of the core and shell is equal to the matrix conductivity. This result is consistent with the finding of Hsu et al. [21] in their comparison of results for the effective thermal conductivity of non-touching solid circular cylinders. In reality, the infinite resistance assumption of the resistors in the normal direction to the applied field introduces a lower bound for the effective conductivity of the system. The accuracy of the solution depends on the conductivity and volume fraction of the phases and geometry under consideration. In contrast to the first approach, the second method overestimates the solution except in the situation mentioned for the first resistor model. Thus, another bound is introduced for the conductivity of the system.

Of particular interest are the situations where the core and shell tend to their limiting conductivity values \((0, +\infty)\). The errors for other cases cannot be much higher than the error for the limiting cases, as is evident from Fig. 5. Thus, the follow-
ing section discusses the ability of the models to predict these limiting cases. Relatively good results can be expected from the first model for the case when both the core and shell have a large conductivity value. Here the accuracy of the solution is tested for a perfectly conducting core and coating layer. Since this case is equal to an array of perfectly conducting solid spheres of radius \(a_1 = a_2\), it is easier to investigate the solution for the alternative system. For this case the effective thermal conductivity can be derived as follows:

\[
K_{1*} = \int_0^{\pi/2} \frac{\sin (2\theta)}{1 - 2a_2 \cos \theta} = -\frac{1}{a_2} - \frac{1}{2a_2^2} \ln (1 - 2a_2) \, d\theta \quad (36)
\]

\[
k_{eff} = -\frac{\pi}{2} \ln (1 - 2a_2) - (\pi a_2^2 + \pi a_2 - 1) . \quad (37)
\]

As was predicted by Batchelor and O’Brien [23], for nearly touching perfectly conducting spheres, the effective thermal conductivity satisfies the following relation:

\[
k_{eff} = -C_1 \ln (1 - 2a_2) - C_2 \quad (a_2 \rightarrow 1/2) \quad (38)
\]

where \(C_1\) and \(C_2\) are two positive constants. The constant \(C_1\) was derived by Batchelor and O’Brien [23] to be \(\pi/2\), and the second constant has been calculated by Sangani and Acrivos [8] to be about 0.69. The first resistor model gives the same value for \(C_1\) but the suggested value for \(C_2\) is equal to 1.356, which is almost twice the value given by Sangani and Acrivos [8]. For this situation, the second resistor model provides the following simple expression:

\[
k_{eff} = \frac{1}{2} \frac{1}{2 - a_2} . \quad (39)
\]

Figure 6 compares the results of the two-resistor model with the data obtained by exact solution and the results of the lower bound given by Hashin and Shtrikman [10].

Since dispersed phases have small conductivity values, a second limiting case can be presented for such dispersed systems. The results of this system have been calculated for the condition where the core and shell are perfectly insulating (an array of perfectly insulating solid sphere of radius placed in a matrix of unit conductivity). It can be seen from Fig. 5 that the second model predicts more accurate results in this situation. From (33) and (35), the following relations for the second model can be derived:

\[
K_{1*} = \int_0^{\pi/2} \frac{\sin \theta}{1 - \pi a_2^2 \sin^2 \theta} = \frac{\pi}{2} \arctan \left( \frac{a_2}{\sqrt{1/\pi - a_2^2}} \right) \quad (40)
\]

\[
k_{eff} = \frac{\pi}{2} \arctan \left( \frac{a_2}{\sqrt{1/\pi - a_2^2}} \right) + (1 - 2a_2) \pi \sqrt{1/\pi - a_2^2} \quad (41)
\]

Also, for the first model one may find:

\[
k_{eff} = 1 - 3a_2^2 . \quad (42)
\]

A comparison between the exact solution with the predicted results based on the two resistor model and two bounds given in [10] for the case of perfectly insulating spheres is shown in Fig. 7.

The results of the resistor models for two rested positions \((k_1 = +\infty, k_2 = 0\) and \(k_1 = 0, k_2 = +\infty\)) are examined in a different way. As can be seen from (15) \(L_{n}^{N}\) plays an important role in the response of the system to the applied field. Due to the shape of mathematical expression (14), for some cases a different series of dispersed phases may exist that gives the same value for \(L_{n}^{N}\). Nicorovici et al. [12] have studied the behaviors of coated spheres. The following discussion considers the case of multi-coated spheres for three scenarios.

1) \(k_{i-1} = k_{i*} \quad (2 \leq i* \leq N - 1) . \quad (43)

After two successive applications of (13) for \(i*\) and \(i* + 1\), the resulting expression for \(L_{n}^{i*+1}\) is:

\[
L_{n}^{i*+1} = \frac{(2n - 1) (k_{i-1},i*+1 - 1) + 2n (k_{i-1},i*+1 + 1) + 1}{(2n - 1) (k_{i-1},i*+1 - 1) + 1} . \quad (44)
\]

Therefore \(L_{n}^{N}\) will not change if these two phases are unified and considered as a unique phase with volume fraction \(4\pi (a_{i*} - a_{i* - 2})/3\). If the core and all coating layers have the same conductivity, the problem can be reduced to the simple array of solid spheres of radius \(a_{N-1}\) immersed in a matrix of unit conductivity.

\[
L_{n}^{N} = \frac{k_1 - 1}{k_1 + 2(n/2n - 1)} . \quad (45)
\]
a simplified expression: has conductivity equal to zero. For this case (44) reduces to
tween the phases $i$ in calculating the and in fact layer
is perfectly conducting. Consequently,
(46)

This result implies that the phases under $i_{\text{max}}$ have no effect in calculating the and in fact layer $i_{\text{max}}$ cuts the relation between the phases $i > i_{\text{max}}$ and $i < i_{\text{max}}$. The first resistor model also shows the same behaviour. For this case, (28) yields the following result:

$$K_i = 0 \quad (i \leq i_{\text{max}}) \, .$$

Thus, these phases play the same role as for the exact solution. In contrast, it can be seen from (33) that the second model does not demonstrate equal behaviour and the results of this model have more errors in this situation.

3) $k_{i_{\text{max}}} = +\infty$, where $i_{\text{max}}$ is the largest coating layer which is perfectly conducting. Consequently,

$$L_{i_{\text{max}}} = 1 \, .$$

Thus, this phase makes the phases under the phase $i_{\text{max}}$ irrelevant in the response of the system to the applied field. In this situation, the second resistor model illustrates similar behaviour. All the region conductivities become infinite:

$$K_i = +\infty \quad (i \leq i_{\text{max}}) \, .$$

Therefore, they do not have any effect on the calculation of the effective thermal conductivity (i.e. (35)). However, the first resistor model is unable to predict this behaviour and the error tends to increase for this condition.

6  Concluding remarks

The method devised by Zuzovski and Brenner [7] has been extended to enable the calculation of the effective conductivity of systems of multi-coated spheres consisting of SC, BCC and FCC unit cells. An explicit expression for the effective thermal conductivity to $O(F^3)$ has been presented. Two resistor models have been developed to obtain alternative solutions to the problem. By inspection of the results of the resistor model and comparison with the results of the exact solution, it was found that the results of these models constitute two bounds for the exact solution. Some scenarios were investigated to identify and discuss situations in which one of these models predicts better results.

The use of a more complex method of analysis, such as combinatorial theory, should help to improve the accuracy of the calculations and provide a more thorough explanation of the physical behaviors of the system. The development of a method based on combinatorial theory and its application to the system studied in this work will be the focus of a future investigation in this area.

Short title: The effective conductivity of composites
Received: January 28, 2003/ Revised: April 8, 2003/ Accepted: May 7, 2003

Abstract

We extend the Rayleigh method for the calculation of the effective conductivity to three-phase composite materials. The materials under study consist of two types of circular cylinders in a periodic arrangement embedded in a matrix. Highly accurate values for lattice sums were obtained using algorithms which have been recently developed. A series of explicit formulations, which are used to facilitate the calculation of the effective conductivity of the composites under study, are reported. We also perform a series of numerical calculations to study the behavior of these composites.

1. Introduction

Multi-phase heterogeneous systems can be found in a wide range of practical processes and are of considerable technological importance. Colloidal dispersions, emulsions, solid rocket propellant, oil-filled porous rocks, concrete, reinforced materials are a few examples of such systems. To handle these systems optimally one needs to know how they behave at the macroscopic level; therefore a great deal of interest has been focused on relating the microstructural and macroscopic properties of these systems, such as the effective thermal, or electrical, conductivity [1,2], dielectric permittivity [3,4] and permeability of a porous medium [5].

One common type of these systems consists of a matrix and a series of dispersed phases. Of these systems those with circular cylinders were among the first to be studied by researchers for deriving the effective conductivity, as is the case in Rayleigh’s studies [1]. Rayleigh took into account a rectangular array of circular cylinders and showed that to completely relate the microstructural and macroscopic properties, the effect of interaction between the cylinders should be taken into account. This fact was later extensively used for obtaining more accurate analytical relations for calculating the effective conductivity of these composite systems [6,7]. Recently, some attempts have been made to generalize the study by developing formulations for multi-phase cases [8]. Clearly, this is an important task since the behavior demonstrated by multi-phase systems can be completely different from that understood on the basis of two-phase systems and further investigation is necessary.

In this research, we are concerned with the problem of calculating the effective conductivity of three-phase periodic structures composed of two types of circular cylinders. The unit cell of the composites under study is a rectangular cylinder with a circular cylinder of type one at the center and a circular cylinder of type two at each corner, as depicted in figure 1. The phases can be solid or stagnant fluid. The configuration of the geometry selected for study makes it possible to construct many periodic structures, which can be widely found in literature. In what follows, we first develop the Rayleigh method to the three-phase composites. Then, we verify the algorithm, comparing our results with some existing results. Finally, we inspect the behavior of the systems. We shall use terms and notations appropriate to the case of thermal conduction for convenience. It is worth noting that the results of this study can be applied to many transport properties besides thermal or electrical conductivity [9,10].

Figure 1. The unit cell of the three-phase composites under study. Cylinders of the same type have a distance equal to a unity in the x-direction and b in the y-direction.
2. Governing equations

Suppose that the origin of cartesian coordinates has been placed at the centre of a cylinder of type one in a unit cell of the system in which the x- and y-axes are parallel to the sides of the unit cell (see figure 1). Furthermore, assume that the matrix of the composite under study has unit conductivity and the periodicity of the system in the y-direction is equal to a unity for greater generality. Applying these conditions, we denote the conductivity of the cylinders by \( k_1 \) and \( k_2 \), the radiuses \( a_1 \) and \( a_2 \) and the volume fractions \( f_1 \) and \( f_2 \) for the cylinders of type one and two, respectively. Also the periodicity of the system in the x-direction will be denoted by \( b \).

For the case \( b \neq 1 \), the effective conductivity of the system in the x-direction (parallel) would be different from that of the y-direction (perpendicular) and one should calculate both these conductivities. In order to simplify the presentation without loss of generality herein, we only consider the parallel direction. The necessary comments for the perpendicular direction shall be outlined in a separate section.

Let us apply a uniform temperature gradient of unit magnitude externally to the system along the x-axis in the negative direction. By taking the center of any cylinder of type \( i \) \((i = 1 \text{ or } 2)\) as the origin of polar coordinates \((r, \theta)\), the temperature within that cylinder and outside it through the matrix can be given as

\[
T_i(r, \theta) = C_{0,i} + \sum_{n=1}^{\infty} C_{2n-1,i} r^{2n-1} \cos (2n-1)\theta
\]

(1)

\[
T_{m,i}(r, \theta) = A_{0,i} + \sum_{n=1}^{\infty} A_{2n-1,i} r^{2n-1} + B_{2n-1,i} r^{-2n+1} \cos (2n-1)\theta,
\]

(2)

where the set of coefficients \( C_{2n-1,i}, A_{2n-1,i} \) and \( B_{2n-1,i} \) are unknowns to be determined. The periodicity of the system implies that these coefficient be exactly the same for all cylinders of the same type. \( C_{0,i} \) and \( A_{0,i} \) express the average of the temperature within the cylinder and outside it, respectively. Thus, they are exactly the same only for cylinders of the same type placed in a column normal to the applied field. In equations (1) and (2), also note that the cosines of the even multiples have been ignored. This is because of anti-symmetric behavior of the temperature around \( \theta = \pi/2 \), where \( \theta \) is measured from the parallel direction.

At the surface of the cylinders, the temperature and the normal component of heat flux are continuous, i.e.,

\[
T_i = T_{m,i}, \quad k_i \frac{\partial T_i}{\partial r} = \frac{\partial T_{m,i}}{\partial r}, \quad r = a_i
\]

(3)

By applying the above-mentioned boundary conditions, we can obtain

\[
A_{2n-1,i} = \frac{B_{2n-1,i}}{\gamma_i a_i^{4n-2}}. \quad (4)
\]
\[ C_{2n-1,i} = \frac{B_{2n-1,i}}{\chi_i a_i^{2n-2}}, \]  
where
\[ \gamma_i = \frac{1-k_i}{1+k_i}, \quad \chi_i = \frac{1-k_i}{2}. \]

For the case of non-conducting cylinders, \( k_i = 0 \), we have \( \gamma_i = 1 \) and \( \chi_i = 0.5 \). Also, applying perfectly conducting cylinders, \( k_i = \infty \), implies that \( \gamma_i = -1 \) and \( \chi_i = -\infty \). The unknown coefficients still cannot be determined since the relations given in equations (4) and (5) do not provide a complete set of equations in terms of the unknowns; we require a further series of relations between the coefficients. For this purpose, we employ Rayleigh’s strategy which is based on the fact that at any point the temperature may be regarded due to external sources and multiple sources placed at the center of the cylinders. By examination of temperature function (2) written for a cylinder, we find that terms with radius raised to a positive power cannot be due to sources placed at the center of that cylinder since they increase when \( r \) increases; therefore they stem from the external field and sources originated from the center of other cylinders. As a result, we can write

\[ A_{0,i} + \sum_{n=1}^{\infty} A_{2n-1,i}r^{2n-1}\cos(2n-1)\theta = x + \]
\[ \sum_{j \neq i} \sum_{n=1}^{\infty} \frac{B_{2n-1,j}}{r_{j,i}^{2n-1}}\cos(2n-1)\theta_{j,i} + \sum_{j \neq i} \sum_{n=1}^{\infty} \frac{B_{2n-1,2-\delta_{j,i}}}{r_{j,2-\delta_{j,i}}^{2n-1}}\cos(2n-1)\theta_{j,2-\delta_{j,i}}, \]  

where \( r_{j,i} \) and \( \theta_{j,i} \) are measured from the center of cylinder \( j \) situated in the array of cylinders of type \( i \). As is specified in equation (7), in the sum over the cylinders of type \( i \), all the cylinders, except the cylinder under study \((j=0)\), should be taken into account but in the sum over the cylinders of the other type, all the cylinders are to be considered without any exception. The above expression can be considered as the real part of the following relation:

\[ A_{0,i} + \sum_{n=1}^{\infty} A_{2n-1,i} \left[x - \xi_{0,i} + i(y - \eta_{0,i})\right]^{2n-1} = \]
\[ x + iy + \sum_{j \neq i} \sum_{n=1}^{\infty} B_{2n-1,j} \left[x - \xi_{0,j} - \xi_{j,i} + i(y - \eta_{0,j} - \eta_{j,i})\right]^{2n+1} + \]
\[ \sum_{j \neq i} \sum_{n=1}^{\infty} B_{2n-1,2-\delta_{j,i}} \left[x - \xi_{0,j} - \xi_{j,2-\delta_{j,i}} + i(y - \eta_{0,j} - \eta_{j,2-\delta_{j,i}}\right]^{2n+1}, \]  

where \( \xi_{j,i} \) and \( \eta_{j,i} \) are the coordinates of cylinder \( j \) of type \( i \) in the coordinate system \((x, y)\). Now we perform successive differentiation with respect to \( x \) on both sides of the above equation and evaluate the results at the center of the cylinder under study \( (\xi_{0,i}, \eta_{0,i}) \). After
applying equation (4), the process yields the following set of linear algebraic equations in the unknowns $B_{2n-1,i}$ ($i = 1,2$):

$$\frac{B_{2n-1,j}}{\gamma_1 a_i^{4n-2}} + \sum_{m=1}^{\infty} \left( \frac{2n + 2m - 3}{2n - 1} \right) S_{2n+2m-2,i} B_{2m-1,i} + S_{2n+2m-2,2} B_{2m-1,2} = \delta_{i1},$$

(9)

where $S_{2,i} = \sum_{j=0}^{\infty} \left( \xi_{j,i} + i \eta_{j,i} \right)^{-2j}$ are lattice sums over cylinders of type $i$. Solving equation (9) and using equations (4) and (5) we can obtain all the unknown coefficients and as result the temperature functions. Since considering $B_{2n-1,i}$ ($i = 1,2$) for a sufficiently large $n$ has no significant effect on the values of the temperature functions, in practice, the system of equations (9) is truncated.

3. Determining the effective conductivity of the system

Based on Fourier’s law, the effective conductivity of the system can be derived using the following formula [11]:

$$\langle F \rangle = -k_e \langle \nabla T \rangle$$

(10)

where $\langle F \rangle = \left(1/V_{cell}\right) \int_{V_{cell}} F dV$ and $\langle \nabla T \rangle = \left(1/V_{cell}\right) \int_{V_{cell}} \nabla T dV$ are the average heat flux and temperature gradient over the unit cell, respectively. To proceed, let us decompose the average heat flux as the following:

$$\langle F \rangle = \frac{1}{V_{cell}} \left[ \int_{V_1} F dV + \int_{V_2} F dV + \int_{V_m} F dV \right]$$

(11)

whence

$$\langle F \rangle = \frac{1-k_1}{V_{cell}} \int_{V_1} \nabla T_1 dV + \frac{1-k_2}{V_{cell}} \int_{V_2} \nabla T_2 dV - \frac{1}{V_{cell}} \int_{V_{cell}} \nabla T dV,$$

(12)

where $V_1$, $V_2$ and $V_m$ are the volumes of cylinders of type one and two and the matrix placed in the unit cell, respectively. After performing the integrals (see appendix A), from equation (12) we may find

$$\langle F \rangle = \frac{2\pi B_{1,1}}{V_{cell}} \textbf{i} + \frac{2\pi B_{1,2}}{V_{cell}} \textbf{i} \cdot \langle \nabla T \rangle$$

(13)

Taking into account that $\langle \nabla T \rangle = \textbf{i}$ and $V_{cell} = b$, the final result for the effective conductivity from equations (13) and (10) can be given as

$$k_e = 1 - 2\pi \left( B_{1,1} + B_{1,2} \right)/b = 1 - 2f_1\gamma_1 A_{1,1} + 2f_2\gamma_2 A_{1,2}$$

(14)
As can be seen from equation (14), knowing $B_{1,1}$ and $B_{1,2}$ is enough for obtaining the effective conductivity of the system. The term $2\pi(B_{1,1} + B_{1,2})/b$ was produced because of the presence of the inclusions in the matrix. It can be positive (impairing case), negative (enhancing case) or equal to zero. For the case in which $N$ types of cylinders are placed in the unit cell, the effective conductivity of the system can be obtained using

$$k_e = 1 - 2\pi \sum_{i=1}^{N} B_{1,i} / V_{cell}$$ (15)

4. The effective conductivity for the perpendicular direction

For deriving the effective conductivity in this direction in order to make it similar with the foregone relations, we rotate the system through an angle of $\alpha = \pi/2$. If we follow the above-mentioned procedures for the parallel direction, we get

$$\frac{B'_{2n-1,j}}{\gamma' a_j^{4n-2}} + \sum_{m=1}^{n-1} \binom{2n + 2m - 3}{2n - 1} S'_{2n+2m-2,l} B'_{2m-1,i} + S'_{2n+2m-2,l} B'_{2m-1,i} = \delta_{n1},$$ (16)

where $S'_{2l,i}$ are lattice sums over cylinders of type $i$ in this new position. It can be proved that $S'_{2l,i} = (-1)^l S_{2l,i}$ for $l > 1$ and also $S'_{2l,i} = 2\pi/b - S_{2l,i}$ (see Refs. [6] and [12]). The effective conductivity of the system may be obtained using the similar formula as (14), i.e.,

$$k'_e = 1 - 2\pi (B'_{1,1} + B'_{1,2})/b$$ (17)

Since the composite under study is a 2-D structure, through a methodology (see appendix B) we can show that the effective conductivity in the perpendicular direction has been linked to that in the parallel direction using the well-know reciprocal theorem of Keller [13-15], i.e.,

$$k_e (k_{1,1}, k_{1,2}, 1) \times k'_e (1/k_{1,1}, 1/k_{1,2}, 1) = 1$$ (18)

5. Explicit solutions

For low-volume fractions or when the conductivity of the cylinders is small, considering a few numbers of $B_{2n-1,1}$ and $B_{2n-1,2}$ in the process of solving (9) may yield reasonable results for $B_{1,1}$ and $B_{1,2}$ and as a result, based on equation (14), for the effective conductivity. It is more useful that, within these boundaries, we manage to derive an explicit relation for the effective conductivity of the system. Based on the method used for truncating (for example square or triangular manner) and on the number of the unknowns taken into account, one may obtain different expressions. If we truncate equation (9) in a triangular manner and keep only the coefficient $B_{1,i}$ and $B_{3,i}$ ($i = 1,2$), we find
Deriving $B_{1,1}$ and $B_{1,2}$ from the above equation and using equation (14), we can obtain the effective conductivity of the system in an explicit relation, i.e.,

$$\frac{B_{1,1}}{\gamma_1 a_1^2} + S_{2,1} B_{1,1} + S_{2,2} B_{1,2} + 3S_{4,1} B_{3,1} + 3S_{4,2} B_{3,2} = 1$$

$$\frac{B_{3,1}}{\gamma_1 a_1^6} + S_{4,1} B_{1,1} + S_{4,2} B_{1,2} = 0$$

$$\frac{B_{1,2}}{\gamma_2 a_2^2} + S_{2,1} B_{1,2} + S_{2,2} B_{1,1} + 3S_{4,1} B_{3,1} + 3S_{4,2} B_{3,2} = 1$$

$$\frac{B_{5,2}}{\gamma_2 a_2^6} + S_{4,1} B_{1,2} + S_{4,2} B_{1,1} = 0$$

(19)

with

$$\lambda_i = \frac{1}{\gamma_i} + c_1 f_i - c_2 \gamma_i f_i^4 - c_3 \gamma_{2-\delta_i} f_i f_{2-\delta_i}^3$$

$$\xi_i = c_4 f_i - c_5 \gamma_i f_i^4 + c_6 f_{2-\delta_i}^3$$

(21)

(22)

where $c_1 = S_{2,1} b / \pi$, $c_2 = 3(b / \pi)^4 S_{4,1}^2$, $c_3 = 3(b / \pi)^4 S_{4,2}^2$, $c_4 = S_{2,2} b / \pi$ and $c_5 = 3S_{4,1} S_{4,2} (b / \pi)^4$. One may leave the higher orders and obtain a simpler relation

$$k_\varepsilon = 1 - \frac{2 f_i}{\omega / \nu_i} - \frac{2 f_2}{\omega / \nu_2},$$

(23)

where

$$\omega = \left(1 / \gamma_1 + c_1 f_i \right)(1 / \gamma_2 + c_1 f_2) - c_2^2 f_i f_2$$

$$\nu_i = 1 / \gamma_i + (c_1 - c_4) f_i$$

(24)

(25)

For the case of uniform cylinders $(f_i = f_2 = f^*, \gamma_1 = \gamma_2 = \gamma^*)$ from equation (20), we obtain the following formula:

$$k_\varepsilon = 1 - \frac{2 F}{1 / \gamma^* + F - d \gamma^* F^4},$$

(26)

where $F = f_i + f_2 = 2 f^*$ is the total volume fraction and $d_i = 3(b / \pi)^4 (S_{4,1} + S_{4,2})^2 / 16$. We have listed $c_1, \ldots, c_5$ for the case $b = \sqrt{3}$ in table 1, calculating highly accurate values for lattice sums using integral representation technique [16]. For this case, $d = 0$ as we expected [6]. Note that equation (20) can also be applied for the perpendicular direction if we calculate the coefficients for this direction. In table 1 we have also reported these values.
Table 1. The calculated values for $c_1, \ldots, c_5$ used in the analytical formula (20) for determining the effective conductivity in the parallel and perpendicular directions for the case $b = \sqrt{3}$.

6. Results and discussions

Before starting the discussion on the results of the three-phase system, it is helpful to verify the validity of the extension to the three-phase system.

Table 2. The calculated lattice sums over cylinders of type one ($S_{n,1}$) and two ($S_{n,2}$) for the case $b = \sqrt{3}$ for $n \leq 40$. The fourth column shows that the sum of these two lattice sums is zero for cases $n \neq 2$ and $n \neq 6m$ ($m = 1, \ldots, \infty$).

</table>
We perform a series of calculations for two-phase composites with uniform cylinders arranged either in square \( (b = 1) \) or hexagonal orders \( (b = \sqrt{3}) \) and then compare the results with those reported by Perrins et al. [6]. The two-phase cases can be constructed from the three-phase one simply by applying \( f_1 = f_2 \) and \( k_1 = k_2 \). For this purpose highly accurate values for lattice sums over cylinders of type one and two were derived and equation (9) \((i=1,2)\) was solved numerically using LU decomposition method [17]. Taking into account 100 unknowns of \( B_{2n+1,1} \) and \( B_{2n-1,2} \) gives us a measure of obtaining accurate results for all the volume fractions and conductivities considered (see Ref. [6]). Table 2 shows a part of the calculated lattice sums used in the procedure of the solutions. In figure 2 the results are compared for both the square and hexagonal arrays for the most challenging case, i.e., the case of perfectly conducting cylinders. As can be seen for all the values of volume fractions, the results of two studies are in excellent agreement.

![Figure 2](image)

**Figure 2.** The effective conductivity of two-phase composites with mono-sized perfectly conducting circular cylinders arranged in square and hexagonal orders. \( F \) shows the volume fraction of the cylinders. The solid lines are the results of Perrins et al. [6] and the dotted lines are those obtained by solving the governing equations of the three-phase composites.

Figure 3 shows a typical result for the effective conductivity of the system for both the parallel and perpendicular directions. The volume fractions are \( f_1 = 0.4 \) and \( f_2 = 0.4 \), and the periodicity in the \( x \)-direction was supposed to be \( b = \sqrt{3} \). For deriving the conductivity of the system in the perpendicular direction we can either solve equation (16) and apply equation (17) or, alternatively, use the Keller theorem for this purpose. Through a careful examination of this figure, it appears that increasing or decreasing the conductivity of the both types of cylinders may enhance or diminish the conductivity of the system, respectively, which is obvious and remains correct for both directions. Furthermore, the system demonstrates higher effective conductivity in the perpendicular direction. This behavior is a consequence of the
rectangular shape of the unit cell which provides a more (less) important role for the cylinders with lower conductivity in the parallel (perpendicular) direction.

Figure 3. The contours of the effective conductivity in the parallel and perpendicular directions for the case of equal sized cylinders. $f_1 = 0.4$, $f_2 = 0.4$ and $b = \sqrt{3}$.

Interestingly, for the case of mono-sized cylinders with $k_1 = \infty$ and $k_2 = 0$, increasing the volume fraction of the cylinders causes the conductivity of the system to approach zero in the parallel direction and approach infinity in the perpendicular direction (see table 3). When perfectly insulating cylinders touch each other, they form a barrier which prevents heat flow in the parallel direction (Note that for the case of spherical inclusions this behavior does not hold true since heat can pass through the gaps between spheres). This behavior can also be observed for all systems for which $b > 1$. For the case $b = 1$, however, the system is isotropic and the same results can be expected for both directions. For this case, the same type cylinders are not able to touch each other and a limited value for the effective conductivity of the system can be expected. Surprisingly, we found that the effective conductivity of the system is simply a unity. This result can be confirmed using the Keller theorem as follows: Since the system is isotropic and interchange between the material of the cylinders keeps the system unchanged, using equation (18) we can get

$$k_e(k_{1/1,1}) \times k_e'(1/k_{1,1}) = k_e(k_{1/1,1}) \times k_e'(k_{1/1,1}) = 1$$

(27)
Table 3. The effective conductivity in the parallel and perpendicular directions, with respect to the total volume fraction ($F$). The cylinders are mono-sized, $k_1 = 0$, $k_2 = \infty$ and $b = \sqrt{3}$ ($b > 1$).

Considering $k = 0$ proves our case. Sculgasser [18] has shown that in a three-phase system with interchangeable phases (see figure 4), when one of the phases has conductivity equal to $k$ and the two remaining phases are perfectly conducting and non-conducting, the effective conductivity of the system is $k$. From the above results, it is clear that it is not necessary for the first phase to be interchangeable, and it can simply be a matrix.

Figure 4. The three-phase structure investigated by Schulgasser et al. [18]. All the phases are interchangeable.

For the case $b = 1$ with non-equal sized cylinders, if $f_i \leq \frac{\pi}{4}\left(\sqrt{2} - 1\right)^2$, $f_{2-6:i}$ can be increased freely to the touching value limit and the effective conductivity of the system can approach infinity or zero, depending on the conductivity of the touching cylinders.
Figure 5 shows the results of the effective conductivity for a system with a lower total volume fraction, i.e., $f_1 = 0.4$ and $f_2 = 0.2$. As before, $b$ is equal to $\sqrt{3}$. Comparing with figure 4 we can see that the case $k_1 = k_2 = 1$ is the only situation in which both systems for the given conductivities present the same effective conductivity. In this situation $\gamma_1 = \gamma_2 = 0$, which leads to $B_{i,1} = B_{i,2} = 0$, and as a result, $k_x = 1$. Figures 3 and 5 also show that having cylinders with conductivities equal to the conductivity of the matrix is not the only condition for the effective conductivity to be equal to the conductivity of the matrix. In fact, this case is a special state of the following general situation:

$$B_{i,1} + B_{i,2} = f_1 \gamma_1 A_{i,1} + f_2 \gamma_2 A_{i,2} = 0$$

(28)

The importance of the situation $k_1 = k_2 = 1$ ($B_{i,1} = B_{i,2} = 0$) is that it is independent of the values of $f_1$, $f_2$ and $b$, and for all these situations, we would find that $k_x = 1$, which is physically obvious. This behavior does not hold for the other values of the conductivities.

![Figure 5](image)

**Figure 5.** The contours of the effective conductivity in the parallel and perpendicular directions for the case of unequal sized cylinders. $f_1 = 0.4$, $f_2 = 0.2$ and $b = \sqrt{3}$.

### 7. Conclusion

The effective conductivity of three-phase composites with circular cylindrical inclusions in a periodic arrangement was derived by extending a method put forwarded by Lord Rayleigh [1]. Considering the recent development in the fast and accurate calculation of lattice sums...
such an extension can be used efficiently for calculating the conductivity of the system. A study of the behavior of the composites revealed that they may exhibit unexpected results in particular states. The structure considered in this study was an ideal one, but the results can be useful for understanding the interplay between microstructures and the effective property of real multi-phase fiber composites and specifically those which can be approximated with the use of periodic structures and circular cylindrical inclusions. Also, the results provide a helpful resource in the process of testing and developing well-known classical numerical methods such as the boundary element method [20] or other proposed schemes in calculating the effective conductivity of multi-phase composite materials.

Appendix A

We would like to calculate the following term:

\[
\langle S \rangle_i = \frac{1 - k_i}{V_{cell}} \int_{V_i} \nabla T_i dV
\]  

(A-1)

By using Green’s first identity [21], the above relation becomes

\[
\langle S \rangle_i = \frac{1 - k_i}{V_{cell}} \int_{\sigma_i} T_i n dS,
\]  

(A-2)

where \( \sigma_i \) is the surface of the cylinder of type \( i \) in the unit cell and \( n \) expresses the unit outward normal vector to the surface. Taking into account the temperature function given in equation (1) and after using the orthogonality properties of trigonometric functions, we can obtain

\[
\langle S \rangle_i = \frac{1 - k_i}{V_{cell}} \int_0^{2\pi} a_i^2 C_{ij} \cos^2 \theta d\theta \frac{\pi a_i^2 (1 - k_i)}{V_{cell}} C_{ij} i = \frac{2\pi B_{i,1}}{V_{cell}} i
\]  

(A-3)

Appendix B

Here extending the procedure given by Perrins et al. [6] we prove Keller’s theorem for the system under study as follows: Considering that reversing the conductivity of the phases only makes the sign of \( \gamma_i (i = 1, 2) \) negative and applying the mentioned property of lattice sums in section 4, from equation (16), we may write

\[
\frac{(-1)^n B_{2n-1,j}}{\gamma_i a_i^{4n-2}} + \sum_{m=1}^{\infty} \binom{2n + 2m - 3}{2n - 1} s_{2n+2m-2,1} (-1)^m B_{2m-1,j} + (-1)^m s_{2n+2m-2,2} B_{2m-1,2-\delta_{ij}} = [1 - 2\pi (B_{1,1} + B_{1,2})/b] \delta_{n1}
\]  

(B-1)

Using equation (17) and comparing the above relation with equation (9), we find that

\[
\frac{B_{2n-1,j}}{k'_e (1/k_1, 1/k_2, 1)} = (-1)^n B_{2n-1,j}
\]  

(B-2)

Writing the above relation for \( n = 1 \) and using again equation (17) we have

\[
k'_e (1/k_1, 1/k_2, 1) = 1 + 2\pi (B_{1,1} + B_{1,2}) k'_e (1/k_1, 1/k_2, 1)/b
\]  

(B-3)
Applying equation (14) gives

\[ k_e(k_1, k_2, 1) \times k'_e\left(\frac{1}{k_1}, \frac{1}{k_2}, 1\right) = 1 \]  \hspace{1cm} (B-4)
Critical resistance for multi-phase composite materials

Received 21 January 2003; received in revised form 22 April 2003; accepted 23 April 2003

Communicated by R. Wu

Abstract

The effect of interfacial resistance on the effective conductivity of a multi-phase composite material was studied. The composite under study is composed of a matrix surrounding different types of circular cylinders arranged in rectangular order. It was assumed that the interfacial resistance is concentrated on the surface of the cylinders. For any direction of calculating the effective conductivity of the system, a condition was found in which the effect of cylinders of one type can be neglected. This condition may be estimated by $R \leq k - 1$, where $R$ and $k$ are the non-dimensional interfacial resistance and the relative conductivity of the neglected cylinders, respectively. The case $R = k - 1$ applies when the same relation exists between the interfacial resistance and conductivity of all types of cylinders.

Keywords: Interfacial resistance; Conductivity; Multi-phase composites

Multi-phase systems, which consist of inclusions of different shapes and properties embedded in a matrix, can be found in a wide range of practical processes and are of considerable technological importance. Starting with the work of Maxwell [1] and Rayleigh [2], who considered the problem of calculating the effective conductivity of two-phase systems composed of spheres and cylinders, McPhedran later extended the discussion to three-phase composites having the CsCl structures [3]. More recently, Whites et al. [4,5], in the context of the dielectric constant, have developed a formulation for the efficient numerical calculation of the effective property of multi-phase composites.

Since the problem of calculating dielectric constant is mathematically identical to that of calculating thermal or electrical conductivity [6,7], similar results can be expected.

Most studies have assumed that the interface is ideal, but the interfacial resistance may occur due to a variety of phenomena [8], such as the presence of a thin gap with a third material between the inclusions and the matrix [9] and disparity in the physical properties [10] (Kapitza resistance). Taking this effect into account is very important, since the effective conductivity may change significantly, and a system with conducting inclusions may behave like one that has non-conducting inclusions.

Chiew [8] showed that for composite materials with a random array of uniform spherical inclusions, there may exist a critical situation in which the system does
not sense the presence of the inclusions. Studies into
the behavior of composites that consist of periodic
arrays of uniform spheres [11,12] and random and
periodic arrays of uniform cylinders [13,14] revealed
that for all these cases a critical situation arises if
the non-dimensional interfacial resistance between the
inclusions and the matrix is equal to the relative
conductivity of the inclusions minus one.

Here, we extend the discussion to multi-phase com-
posite materials. In order to simplify the presenta-
tion, let us consider a three-phase system that con-
ists of a matrix and two types of circular cylindri-
cal inclusions that are arranged in rectangular order
with periodicities equal to a unity in the y-direction
and b in the x-direction, as depicted in Fig. 1. Let
us assume that a uniform field of magnitude $E_{\text{ext}}$ has
been applied along the x-axis in the negative direc-
tion. At the surface of any cylinder of type $i$ ($i=1,2$),
we may consider a dimensionless interfacial resis-
tance [15], $R_i$, and express the boundary conditions
as follows:

$$
\frac{k_i}{R_i a_i} (T_i - T_m) = -k_i \frac{\partial T_i}{\partial r} = -\frac{\partial T_m}{\partial r}, \quad r=a_i, \quad (1)
$$

where $a$ and $k$ represent the radius and the relative
conductivity of cylinders, respectively. $T$ shows the
temperature function and $m$ refers to the matrix. Us-
ing the Rayleigh method for the purpose of solving the
Laplace equation through the system provides a sys-
tem of algebraic equations in which the $n$th equation
$(n = 1, \ldots, \infty)$ of the set reads

$$
\frac{B_{2n-1}'^i}{\gamma_{2n-1}^i a_{2n-1}^i} + \sum_{m=1}^{\infty} \left( \frac{2n+2m-3}{2n-1} \right) B_{2m-1}'^i \\
\times \left( S_{2n+2m-2}^i B_{2m-1}'^i + S_{2n+2m-2}^i B_{2m-1}'^i \right) = E_{\text{ext}} \delta_{n1}, \quad (2)
$$

where $B_{2n-1}'^i$ are unknowns, $S_{2n}^i$ are the lattice sums
[1] over cylinders of type $i$, $\delta_{ij}$ represents the Kro-
neck delta (1 for $i=j$, otherwise 0) and $\gamma_{2n-1}^i$, which can be referred to as multipolar polarizabilities,
are of the form

$$
\gamma_{2n-1}^i = \frac{1 - k_i + R_i (2n-1)}{1 + k_i + R_i (2n-1)}. \quad (3)
$$

By applying the Fourier law, the effective conduc-
tivity of the system can be derived as follows:

$$
k_e = 1 - \frac{2 \pi (B_1^i + B_2^i)}{b E_{\text{ext}}}. \quad (4)
$$

or more generally, for the case of $N$ types of cylinders
in the unit cell as $k_e = 1 - 2 \pi \sum_{i=1}^{N} \frac{B_i'(b E_{\text{ext}})}{b E_{\text{ext}}}$ The values of $B_1^i$ and $B_2^i$ can be obtained numerically by solving
the algebraic system of equations given in (2),
however, coarsely truncating (2), we may explicitly
derive these values. If we perform a triangular trun-
cation of the second order of (2) and use the resultants
$B_1^i$ and $B_2^i$ in (4), we can obtain an analytical rela-
tion for the effective conductivity, which can be applied
to low-volume fractions, i.e.,

$$
k_e = 1 - \sum_{i=1}^{2} \frac{2 f_i}{\lambda_i (\lambda_2 - \delta_2) - \xi_i (\delta_2 - \xi_2)} \quad (5)
$$

with

$$
\lambda_i = \frac{1}{\gamma_{1i}^i} + c_1 f_i - c_2 \gamma_{1i}^i f_i^4 - c_3 \gamma_{2i}^i f_i f_3^2 f_i^2, \quad (6)
$$

$$
\xi_i = c_4 f_i - c_5 \gamma_{1i}^i f_i^4 + \gamma_{2i}^i f_i f_3^2 f_i^2. \quad (7)
$$

where $f_i$ denotes the volume fraction of cylinders
of type $i$. The constants for the case $b = \sqrt{3}$ for
deriving the effective conductivity in the $x$-(parallel)
and $y$-(perpendicular) directions are listed in Table 1,
calculating highly accurate values for the lattice sums
using integral representation technique [16].

Fig. 2 shows the results for the effective conduc-
tivity in the presence of the interfacial resistance. The
the system is less than the conductivity of the phases (see interfacial resistances are very large, the effective conductivity of and perpendicular directions for the case $b = \sqrt{3}$). The calculated values for $c_1, \ldots, c_5$ used in the analytical formula (5) for determining the effective conductivity in the parallel and perpendicular directions for the case $b = \sqrt{3}$ are given in Table 1. The contours of the effective conductivity with respect to the interfacial resistance of the cylinders. Fig. 2. This means that the effective conductivity can be calculated simply by using $k_e = 1 - 2\pi B_1^2/(\delta_1 E_{ext})$ but for the imperfect interface case, the terms $B_{2n-1}^2 (n > 1)$ are not zero and are present in the procedure of the calculation of $B_1^{2-\delta_2}$, as is evident in Eq. (2). For the perfect interface case, all the terms of $B_{2n-1}^2 (n > 1)$ are zero and do not affect the value of $B_1^{2-\delta_2}$. This means that the field distributions inside the matrix for the two- and three-phase systems may be dissimilar. The degree of discrepancy can only be numerically determined and depends on the geometrical considerations, resistance and conductivity of the inclusions. Fig. 3 shows a comparison between the effective conductivity of the two systems for a series of given data. As can be seen, the results for the three-phase system underestimate the conductivity of the two-phase system. The reason can be understood when considering that for the three-phase case $\gamma_1^{2n-1} > 0 (n > 1)$, while for the two-phase one they are zero. Increasing $f_i$ increases the error, since the higher-order terms play an important role in the response of the system. In the dilute limit, the systems can be used equivalently. This is also evident from Eq. (5), as ignoring the higher orders for the case $\gamma_1^i = 0$ gives $k_e = 1 - 2\pi f_2/(b E_{ext})$, which is the conductivity of the system, which neglects the effect of the type-$i$ inclusions.
By reducing $R_i$ from the value $k_i - 1$, we may obtain a situation in which the three-phase system exactly gives the effective conductivity of the two-phase one. The expectation of finding such a situation stems from the fact that cylinders the conductivity of which is greater than that of the matrix, boost the conductivity of the system. Fig. 4 reports such an interfacial resistance for type-two cylinders as a function of the interfacial resistance of type-one cylinders for another series of given data. As can be seen, only when $R_1 = k_1 - 1$, we get $R_2 = k_2 - 1$.

For the case of $N$ types of cylinders in the unit cell, by extending Eqs. (2) and (4), it can be shown that when $R_i = k_i - 1$ ($i = 1, \ldots, N$), the effect of all types of cylinders can be neglected and the system simply behaves like a homogeneous system with the conductivity of the matrix. In other cases, the resistance, in which the effect of type-$i$ cylinders in the direction of the calculation the effective conductivity can be neglected, may be estimated by $R_i < k_i - 1$.

In summary, the effective conductivity of a multiphase composite material that is made up of a periodic structure in the presence of the interfacial resistance was studied. The situations in which the effect of one or all types of cylinders can be neglected due to the interfacial resistance were explained. The structure considered in this study was composed of circular cylinders in a periodic arrangement, but when the results given in Refs. [11–14] are considered, a similar outcome can be expected for the case of random arrangements as well as for that of spherical inclusions (random and periodic).

Short title: Transport property; Coated system.

Abstract

This paper reports a series of investigations into the effective transport properties of composite materials with coated inclusions. The geometry of the inclusions under study are circular cylindrical, elliptical cylindrical and spherical. The method we use for this study extends the theorems or exact solutions given for two-phase systems. It is shown that only in a few cases coated composites exhibit the same behavior.

1. Introduction

Determining the response of composite systems to an imposed field has long been of interest from both the theoretical and applied standpoints. The problem arises when studying a variety of phenomena in physics [1-3], mathematics [4,5], biology [6] and engineering [7]. In many cases it is necessary to coat the inclusions; one such case is for the purpose of increasing the wettability and adhesion of the inclusions and the matrix. When the enhancing effect of the inclusions is not sufficient, a coating layer may modify the behaviour of the system. For protection from chemical reactions, a suitable coating layer can also be applied. In some cases, the coating layer is unwanted but occurs because of many problems in the production processes. For instance, due to a mismatch in thermal expansion, a coating layer with a third material may appear between the inclusions and the matrix. In some cases, modelling a system as a coated one may provide reasonable results, even though the system is not exactly coated. This is the case for wet wood for which the moisture is considered to be a coating layer. Therefore, extending the formulations to coated systems and inspecting behavior of these systems may have many implications.

In this research, we consider coated composite systems and inspect some of the behaviour of these systems. The formulations have been given in the context of dielectric constant for greater generality [8].

2. Analysis

Consider a statistically homogeneous composite material that consists of a random array of cylinders with arbitrary cross-sections embedded in a host medium. The dielectric constants of the layers are \( \varepsilon_i \) (\( i = 1,2 \)) where \( i = 1 \) stands for the core and \( i = 2 \) for the matrix. Mendelson [9] has shown that Keller’s reciprocal theorem [10] is valid for the system. Therefore we can write the following:

\[
\epsilon_{\text{eff}}^x (\epsilon_1, \epsilon_2) \times \epsilon_{\text{eff}}^y (1/\epsilon_1, 1/\epsilon_2) = 1
\]

where \( \epsilon_{\text{eff}}^x \) and \( \epsilon_{\text{eff}}^y \) are the effective dielectric constants in the direction of the principal axes \( x \) and \( y \), respectively. The mathematical basis for the proof of this behaviour is the observation that any two-dimensional divergence-free field, when rotated locally at each point by 90°, produces a curl-free field and vice versa [11]. If we develop this result to multiply coated systems we obtain

\[
\epsilon_{\text{eff}}^x (\epsilon_1, \ldots, \epsilon_N) \times \epsilon_{\text{eff}}^y (1/\epsilon_1, \ldots, 1/\epsilon_N) = 1
\]

where \( N \) stands for the matrix (see also Lu [12] and Fel et al. [13]). Considering the following general rule

\[
\epsilon_{\text{eff}}^y (\alpha_i \epsilon_1, \ldots, \alpha_i \epsilon_i, \ldots, \alpha_N \epsilon_N) = \alpha_i \epsilon_{\text{eff}}^y (\alpha_i \epsilon_1, \ldots, \epsilon_i, \ldots, \alpha_N \epsilon_N)
\]

where \( \alpha_{i,j} = \alpha_i / \alpha_j \), we may also derive
If the medium is statistically isotropic, relation (2) can be rewritten as

\[ \varepsilon_{\text{eff}} (\varepsilon_1, \ldots, \varepsilon_N) = \varepsilon_{\text{eff}} (1/\varepsilon_1, \ldots, 1/\varepsilon_N) = 1 \]  

(5)

The behaviour expressed in Eq. (2) and the resultant relations adhere to the following general facts that can be applied to any coated composites. When one layer is perfectly insulating or conducting, the layers under this layer will have no affect in the transport property of the system. Secondly, if two layers have the same dielectric constant, they can be considered to be a unit layer.

For composites consisting of a random array of singly coated circular cylinders, Nicorovici et al. [14] proved that, by coating the cores with the material of the core or its negative, the same effective dielectric constant may be achieved. This behaviour can be formulated as

\[ \varepsilon_{\text{eff}}^x (\varepsilon_1, \varepsilon_2) \times \frac{1}{\varepsilon_{\text{eff}}^x (\pm \varepsilon_1, \pm \varepsilon_2)} = 1 \]  

(6)

\[ \varepsilon_{\text{eff}}^y (\varepsilon_1, \varepsilon_2) \times \frac{1}{\varepsilon_{\text{eff}}^y (\pm \varepsilon_1, \pm \varepsilon_2)} = 1 \]  

(7)

Our attempt [15] to extend the results to multiply coated cylinders showed that coating the cores with a series of layers, which have the same property as the core or its negative, may yield the same response to the applied field. For example, the following doubly coated systems all have exactly the same dielectric constant:

\[ \varepsilon_1, \varepsilon_1, \varepsilon_2 \]
\[ \varepsilon_1, -\varepsilon_1, \varepsilon_2 \]
\[ \varepsilon_1, \varepsilon_1, -\varepsilon_2 \]
\[ \varepsilon_1, -\varepsilon_1, -\varepsilon_2 \]

This means that

\[ \varepsilon_{\text{eff}}^x (\varepsilon_1, \varepsilon_1, \varepsilon_2) \times \frac{1}{\varepsilon_{\text{eff}}^x (\pm \varepsilon_1, \pm \varepsilon_1, \pm \varepsilon_2)} = 1 \]  

(9)

\[ \varepsilon_{\text{eff}}^y (\varepsilon_1, \varepsilon_1, \varepsilon_2) \times \frac{1}{\varepsilon_{\text{eff}}^y (\pm \varepsilon_1, \pm \varepsilon_1, \pm \varepsilon_2)} = 1 \]  

(10)

Using relation (2) we may also find that

\[ \varepsilon_{\text{eff}}^z (\varepsilon_1, \varepsilon_1, \varepsilon_2) \times \varepsilon_{\text{eff}}^y (1/\varepsilon_1, \pm 1/\varepsilon_1, \pm 1/\varepsilon_1, 1/\varepsilon_2) = 1 \]  

(11)

The proof of the behaviour outlined in Eqs. (9) and (10) is different from that given for Eqs. (1) and (2) and is based on deriving the effective dielectric constant of
the system. Herein, we briefly explain the method for the composites with square array of multiply coated circular cylinders. The effective dielectric constant of the system can be calculated using $\varepsilon_{\text{eff}} = 1 - 2\pi B_i^N$ which is the result of Green’s theorem [16]. $B_i^N$ is an unknown that can be obtained by solving the following set of linear equations [17]:

$$\xi_{2n-1}^N B_{2n-1}^N + \sum_{m=1}^{\infty} \frac{(2n + 2m - 3)l}{(2m - 2)l(2n - 1)l} S_{2n+2m-2} B_{2m-1}^N = \delta_{n1}$$ (12)

where $\delta_{n1}$ represents the Kronecker delta (1 for n=1, otherwise 0), $S_n$ are the lattice sums [16,17] and $a_i$ is the radius of layer $i$. The coefficients $\xi_{2n-1}^N$ can be obtained by successively applying the following procedure which is the result of implementing the boundary conditions between the layers:

$$\xi_{2n-1}^i = \frac{(\varepsilon_i - \varepsilon_{i-1}) + (\varepsilon_i + \varepsilon_{i-1}) \xi_{2n-1}^{i-1} a_i^{4n-2}}{(\varepsilon_i + \varepsilon_{i-1}) + (\varepsilon_i - \varepsilon_{i-1}) \xi_{2n-1}^{i-1} a_i^{4n-2}} \times \frac{1}{a_i^{4n-2}}$$ (13)

For all the cases given in (8), relation (13) can be reduced to $\xi_{2n-1}^i = (\varepsilon_i + \varepsilon_i)/[\varepsilon_i - \varepsilon_i] d_i^{4n-2]$ which is exactly equal to that given for solid cylinders of radius $a_i$. Since the other parameters remain unchanged, all the cases yield the same $B_i$ and, as a result, the same dielectric constant can be expected for all of them. We have numerically verified the above theorems. Our numerical investigations show that it is not necessary for the system to be composed only of coated cylinders. Other geometries, which do not interrupt coated cylinders, can also be included in the system.

The above bring up the question as to whether one can expect the same behaviour for all composites with cylindrical inclusions. Among a few potential geometries for analytical inspection, we rather consider elliptical inhomogenities [18] since the solution is given based on the Rayleigh method. Because of the anisotropy, we are concerned with two series of relations for $\xi$, i.e.

$$\xi_{n1}^{x,2} = \frac{\varepsilon_2 \cosh(n\mu_1) + \varepsilon_1 \sinh(n\mu_1)}{(\varepsilon_2 - \varepsilon_1) \sinh(2n\mu_1)} \times \frac{1}{(c/2)^2 e^{\mu_1}}$$ (14)

$$\xi_{n1}^{y,2} = \frac{\varepsilon_2 \cosh(n\mu_1) + \varepsilon_1 \sinh(n\mu_1)}{(\varepsilon_2 - \varepsilon_1) \sinh(2n\mu_1)} \times \frac{1}{(c/2)^2 e^{\mu_1}}$$ (15)

where $(\mu, \theta)$ are elliptic cylindrical coordinates and $c$ is the distance between the two foci. Here we develop the solution to a multiply coated system. The results can be expressed as
Using the relations \( \lim_{\epsilon \to 0} \epsilon^{-\mu_{l-1}} = 0 \) and \( \lim_{\mu \to 0} \epsilon^{-\mu_{l-1}} = 0 \), one can show that in the
limit, both \( \xi_{n,j}^{x,i} \) and \( \xi_{n,j}^{y,i} \) will be reduced exactly to the corresponding relation given for circular cylinders (i.e. Eq. (13)). But substituting the relations \( \epsilon_i = -\epsilon_{i-1} \) \((i = 2, \ldots, N-1)\) for an arbitrary \( c \) and \( \mu \) does not reduce \( \xi_{n,j}^{x,i} \) and \( \xi_{n,j}^{y,i} \) to the shape of the formulations given for a two-phase system (i.e. Eqs. (14) and (15)). Therefore, the above-mentioned behaviour for circular cylinders cannot be applied for all coated composites with cylindrical inclusions. In figures 1 (a, b) this fact has been verified. As can be seen, changing the dielectric constant of the coating layer from \( \epsilon_2 = \epsilon_1 \) to \( \epsilon_2 = -\epsilon_1 \) alters the field through the matrix. The equivalent system for the case \( \epsilon_2 = -\epsilon_1 \) can only be numerically determined.

Fig. 1. The equipotential contours inside the unit cell of a system composed of singly coated elliptical cylinders. A potential gradient of unit magnitude was applied externally along the \( x \)-axis and other external boundaries were insulated. (a) \( \epsilon_2 = \epsilon_1 \)
(b) \( \epsilon_2 = -\epsilon_1 \).
Now we consider composites with coated spherical inclusions. The behavior given in Eq. (2) is not valid for these composites [19]. Also, it has been shown that relations (6) and (7) are not applicable for composites with spherical inclusions [14]. The equivalent system again can only be numerically determined. However, in the dilute limit, where we can assume that there is no interaction between the spheres, cases $\varepsilon_2 = -0.5\varepsilon_1$ and $\varepsilon_2 = \varepsilon_1$ give the same response to the applied field. If we develop the solution given for the solid spheres [20] to multiply coated spheres, the corresponding $\xi_{n^{-1}}$ can be obtained as

$$
\xi_{2n^{-1}} = \frac{2n(\varepsilon_i - \varepsilon_{i-1}) + \xi_{2n^{-1}}\left[2n(\varepsilon_i - \varepsilon_{i-1}) + 2n\varepsilon_i\right]}{2n\varepsilon_i + (2n-1)\varepsilon_i} + \xi_{2n^{-1}}\left[2n(\varepsilon_i - \varepsilon_{i-1})\varepsilon_i - \varepsilon_{i-1}\right]a_{i-1}\times \frac{1}{a_{i-1}} \tag{19}
$$

By substituting $\varepsilon_i = -0.5\varepsilon_{i-1}$ ($i = 3, \ldots, N-1$) for $n=1$ in Eq. (19) one can show that the above-mentioned behaviour for composites with singly coated spherical inclusions cannot be extended to multiply coated spheres. We also argue that applying the above conditions for multiply coated systems means that, for infinitely coated layers, the property of the outermost coating layer tends to be zero. As mentioned before, this layer has the property of impeding the effects of the other coating layers in the dielectric constant of the system. Therefore, the dielectric constant of the system cannot be equal to that of a system consisting of spheres with the property of the core.

3. Conclusion

The behaviour of coated composites in a viewpoint can be divided into two main groups of which one is applicable to every coated system and the other to those which are valid just for one or a series of coated systems. The restrictions in the behaviour outlined in this research were the dimension, concentration and geometry.
